MariaDB Server Documentation

Quickstart Guides

- Installing MariaDB Server Guide
- Adding & Changing Data Guide
- Essential Queries Guide
- Basics Guide
- Altering Tables Guide
- Connecting to MariaDB Guide
- Troubleshooting Connection Issues Guide
- Doing Time Guide
- Importing Data Guide
- Essentials of an Index Guide
- Getting Started with Indexes Guide
- Joining Tables with JOIN Clauses
- Advanced Joins
- Configuring MariaDB for Remote Client Access Guide
- Getting Data Guide
- Basic SQL Statements Guide
- Basic SQL Debugging Guide
- MariaDB String Functions Guide
- Restoring Data from Dump Files Guide
- Changing Times in MariaDB
- System & Status Variables Guide
- Making Backups with mariadb-dump Guide
- A MariaDB Primer Guide
- Creating & Using Views Guide
- Database Applications
  - Introduction & Background
  - Database Design
  - Application Code
  - Canary Testing

Server Usage

- Basics
  - Basic Queries
- Backup & Restore
  - Backup and Restore Overview
  - Forming a Backup Strategy
  - Backup Optimization
  - MariaDB Enterprise Backup
  - mariadb-backup
    - mariadb-backup Overview
    - mariadb-backup Options
    - Full Backup and Restore (mariadb-backup)
    - Incremental Backup and Restore (mariadb-backup)
    - Partial Backup and Restore (mariadb-backup)
    - Point-In-Time Recovery (PITR, mariadb-backup)
    - Restoring Individual Databases From a Full Backup (mariadb-backup)
    - Restoring Individual Tables and Partitions (mariadb-backup)
    - Setting up a Replica (mariadb-backup)
    - Files Backed Up by mariadb-backup
    - Files Created by mariadb-backup
    - Using Encryption and Compression Tools With mariadb-backup
    - Encrypted Files Backup (mariadb-backup)
    - How mariadb-backup Works
    - mariadb-backup and BACKUP STAGE
  - Point-In-Time Recovery (InnoDB Log Archiving)
  - Replication as a Backup Solution
  - Backup and Restore via dbForge Studio
- Tables
  - Copying Tables Between Databases and Servers
  - ALTER TABLE
  - CREATE TABLE
  - DROP TABLE
  - Data Types
  - Storage Engines
- Partitioning Tables
  - Partitioning Overview
  - Partition Pruning and Selection
  - Partition Maintenance
  - Partitioning Types
    - Partitioning Types Overview
    - HASH Partitioning Type
    - KEY Partitioning Type
    - LINEAR HASH Partitioning Type
    - LINEAR KEY Partitioning Type
    - LIST Partitioning Type
    - RANGE COLUMNS and LIST COLUMNS Partitioning Types
    - RANGE Partitioning Type
  - Partitioning Limitations
  - Partitions Files
  - Partitions Metadata
- Stored Routines
  - Stored Procedures
    - Stored Procedure Overview
    - CREATE PROCEDURE
    - ALTER PROCEDURE
    - DROP PROCEDURE
  - Stored Functions
    - Stored Function Overview
    - Stored Aggregate Functions
    - Stored Routine Privileges
    - DROP FUNCTION
    - Stored Function Limitations
  - Binary Logging of Stored Routines
  - Stored Routine Limitations
  - DBMS_OUTPUT
  - Storage Engines Overview
  - Choosing the Right Storage Engine
  - ARCHIVE
  - ARIA
    - Aria Storage Engine
    - Aria Group Commit
    - Aria Status Variables
    - Aria Storage Formats
    - Aria System Variables
    - Aria Two-step Deadlock Detection
    - Aria FAQ
    - The Aria Name
  - BLACKHOLE
  - CONNECT
    - Introduction to the CONNECT Engine
    - Using CONNECT
      - Using CONNECT - Condition Pushdown
      - Using CONNECT - Exporting Data From MariaDB
      - Using CONNECT - General Information
      - Using CONNECT - Importing File Data Into MariaDB Tables
      - Using CONNECT - Indexing
      - Using CONNECT - Partitioning and Sharding
      - Using CONNECT - Virtual and Special Columns
    - Installing CONNECT

- CONNECT Create Table Options
- CONNECT Data Types
- CONNECT Table Types
  - CONNECT Table Types Overview
  - CONNECT BIN Table Type
  - CONNECT CSV and FMT Table Types
  - CONNECT DBF Table Type
  - CONNECT DOS and FIX Table Types
  - CONNECT - External Table Types
  - CONNECT - Files Retrieved Using Rest Queries
  - CONNECT INI Table Type
  - CONNECT JDBC Table Type: Accessing Tables from Another DBMS
  - CONNECT JSON Table Type
  - CONNECT MONGO Table Type: Accessing Collections from MongoDB
  - CONNECT MYSQL Table Type: Accessing MySQL/MariaDB Tables
  - CONNECT - NoSQL Table Types
  - CONNECT OCCUR Table Type
  - CONNECT ODBC Table Type: Accessing Tables From Another DBMS
  - CONNECT PIVOT Table Type
  - CONNECT PROXY Table Type
  - CONNECT Table Types - Catalog Tables
  - CONNECT Table Types - Data Files
  - CONNECT Table Types - OEM: Implemented in an External LIB
  - CONNECT Table Types - Special "Virtual" Tables
  - CONNECT Table Types - VIR
  - CONNECT TBL Table Type: Table List
  - CONNECT - Using the TBL and MYSQL Table Types Together
  - CONNECT VEC Table Type
  - CONNECT XCOL Table Type
  - CONNECT XML Table Type
  - CONNECT Zipped File Tables
  - Inward and Outward Tables
- CONNECT Security
- CONNECT System Variables
- Adding the REST Feature as a Library Called by an OEM Table
- Compiling JSON UDFs in a Separate Library
- Making the GetRest Library
- OEM Table Example
- Current Status of the CONNECT Handler
- JSON Sample Files

CSV
- CSV Overview
- Checking and Repairing CSV Tables

DuckDB

FederatedX
- About FederatedX
- Differences Between FederatedX and Federated

InnoDB
- InnoDB Introduction
- InnoDB File Format
- InnoDB Limitations
- AUTO_INCREMENT Handling in InnoDB
- Binary Log Group Commit and InnoDB Flushing Performance
- InnoDB Asynchronous I/O
- InnoDB Buffer Pool
- InnoDB Change Buffering
- InnoDB Data Scrubbing
- InnoDB Doublewrite Buffer
- InnoDB Flush Method
- InnoDB Lock Modes
- InnoDB Log Archiving
- InnoDB Monitors
- InnoDB Page Compression
- InnoDB Page Flushing
- InnoDB Purge
- InnoDB Undo Log
- InnoDB Redo Log
- InnoDB Strict Mode
- InnoDB System Variables
- InnoDB Versions
- InnoDB Architecture for MariaDB Enterprise Server
  - MariaDB Enterprise Server InnoDB Background Thread Pool
  - MariaDB Enterprise Server InnoDB I/O Threads
- InnoDB Online DDL
  - InnoDB Online DDL Overview
  - InnoDB Online DDL Operations with the INPLACE Alter Algorithm
  - InnoDB Online DDL Operations with the INSTANT Alter Algorithm
  - InnoDB Online DDL Operations with the NOCOPY Alter Algorithm
  - Instant ADD COLUMN for InnoDB
- InnoDB Row Formats
  - InnoDB Row Formats Overview
  - InnoDB COMPACT Row Format
  - InnoDB COMPRESSED Row Format
  - InnoDB DYNAMIC Row Format
  - InnoDB REDUNDANT Row Format
  - Troubleshooting Row Size Too Large Errors with InnoDB
- InnoDB Tablespaces
  - InnoDB File-Per-Table Tablespaces
  - InnoDB System Tablespaces
  - InnoDB Temporary Tablespaces
- InnoDB Troubleshooting
  - InnoDB Troubleshooting Overview
  - InnoDB Data Dictionary Troubleshooting
  - InnoDB Recovery Modes
- MariaDB Enterprise Server InnoDB Operations
  - Configure the InnoDB Buffer Pool
  - Configure the InnoDB I/O Threads
  - Configure the InnoDB Purge Threads
  - Configure the InnoDB Redo Log
  - Configure the InnoDB Undo Log
  - Schema Changes
    - InnoDB Schema Changes
  - InnoDB - Unmaintained
    - About XtraDB
    - Using InnoDB Instead of XtraDB

MEMORY

MERGE

Mroonga
- Mroonga Overview
- About Mroonga
- Mroonga Status Variables
- Mroonga System Variables
- Mroonga User-Defined Functions
  - Creating Mroonga User-Defined Functions
  - last_insert_grn_id
  - mroonga_command
  - mroonga_escape
  - mroonga_highlight_html
  - mroonga_normalize
  - mroonga_snippet
  - mroonga_snippet_html

MyISAM
- MyISAM Overview

- MyISAM Index Storage Space
- MyISAM Storage Formats
- MyISAM System Variables
- MyRocks
  - About MyRocks for MariaDB
  - Building MyRocks in MariaDB
  - Differences Between MyRocks Variants
  - Getting Started with MyRocks
  - Loading Data Into MyRocks
  - MyRocks Bloom Filters
  - MyRocks CHECK TABLE
  - MyRocks Data Compression
  - MyRocks Group Commit with Binary log
  - MyRocks Index-Only Scans
  - MyRocks and Replication
  - MyRocks START TRANSACTION WITH CONSISTENT SNAPSHOT
  - MyRocks Column Families
  - MyRocks Performance Troubleshooting
  - Optimizer Statistics in MyRocks
  - MyRocks Transactional Isolation
  - MyRocks Status Variables
  - MyRocks System Variables
- OQGRAPH
  - OQGRAPH Overview
  - Installing OQGRAPH
  - Compiling OQGRAPH
  - Building OQGRAPH Under Windows
  - OQGRAPH Examples
- PERFORMANCE_SCHEMA
- SEQUENCE Storage Engine
- S3 Storage Engine
  - Using the S3 Storage Engine
  - S3 Status Variables
  - S3 System Variables
  - S3 Engine Internals
  - Testing Connections to S3
  - aria_s3_copy
- SphinxSE
  - About SphinxSE
  - Installing Sphinx
  - Installing and Testing SphinxSE with MariaDB
  - Configuring Sphinx
- Spider
  - Spider Storage Engine Overview
  - Spider Storage Engine Introduction
    - MariaDB Enterprise Spider Schema Design
    - MariaDB Enterprise Spider Operations
      - Federated MariaDB Enterprise Spider Topology Operations
      - Spider Federated Overview
      - Federated MariaDB Enterprise Spider Topology Backup and Restore
      - Federated MariaDB Enterprise Spider Topology Migrate Tables
      - ODBC MariaDB Enterprise Spider Topology Operations
      - Use Spider ODBC to Connect to Oracle
      - Sharded MariaDB Enterprise Spider Topology Operations
      - Spider Sharded Overview
      - Sharded MariaDB Enterprise Spider Topology Add a Shard
      - Sharded MariaDB Enterprise Spider Topology Backup and Restore
  - Spider Differences Between SpiderForMySQL and MariaDB
  - Spider Feature Matrix
  - Spider Use Cases
  - Spider Installation
  - Spider Cluster Management
  - Spider Case Studies
  - Spider Benchmarks
  - Information Schema SPIDER_WRAPPER_PROTOCOLS Table
  - Spider Storage Engine Core Concepts
  - Spider System Variables
  - Spider Table Parameters
  - Spider Functions
    - SPIDER_BG_DIRECT_SQL
    - SPIDER_COPY_TABLES
    - SPIDER_DIRECT_SQL
    - SPIDER_FLUSH_TABLE_MON_CACHE
  - Spider FAQ
- VIDEX Storage Engine
- Converting Tables from MyISAM to InnoDB
- Machine Learning with MindsDB
- FEDERATED Storage Engine
- Triggers & Events
  - Event Scheduler
    - Events Overview
    - ALTER EVENT
    - Event Limitations
  - Triggers
    - Trigger Overview
    - CREATE TRIGGER
    - Trigger Limitations
    - Triggers and Implicit Locks
- User-Defined Functions
  - User-Defined Functions Overview
  - Creating User-Defined Functions
  - CREATE FUNCTION UDF
  - DROP FUNCTION UDF
  - User-Defined Functions Calling Sequences
  - User-Defined Functions Security
- Views
  - ALTER VIEW
  - CREATE VIEW
  - DROP VIEW
  - Information Schema VIEWS Table
  - Inserting and Updating with Views
  - View Algorithms

Server Management

- Security Vulnerabilities (CVE) Fixed in MariaDB Community Server
- Security Vulnerabilities (CVE) Fixed in Oracle MySQL That Did Not Exist in MariaDB

Architecture

- Topologies
- Topologies Overview
- Compatibility
- Columnstore Object Storage
- Step 1: Prepare ColumnStore Nodes
- Step 2: Configure Shared Local Storage
- Step 3: Install MariaDB Enterprise Server
- Step 4: Start and Configure MariaDB Enterprise Server
- Step 5: Test MariaDB Enterprise Server
- Step 6: Install MariaDB MaxScale
- Step 7: Start and Configure MariaDB MaxScale
- Step 8: Test MariaDB MaxScale
- Step 9: Import Data
- ColumnStore Shared Local Storage
- Step 1: Prepare ColumnStore Nodes
- Step 2: Configure Shared Local Storage
- Step 3: Install MariaDB Enterprise Server
- Step 4: Start and Configure MariaDB Enterprise Server
- Step 5: Test MariaDB Enterprise Server
- Step 6: Install MariaDB MaxScale
- Step 7: Start and Configure MariaDB MaxScale
- Step 8: Test MariaDB MaxScale
- Step 9: Import Data
- Galera Cluster
- Step 1: Install MariaDB Enterprise Server
- Step 2: Start and Configure MariaDB Enterprise Server
- Step 3: Test MariaDB Enterprise Server
- Step 4: Install MariaDB MaxScale
- Step 5: Start and Configure MariaDB MaxScale
- Step 6: Test MariaDB MaxScale
- HTAP
- Step 1: Prepare ColumnStore Node
- Step 2: Install MariaDB Enterprise Server
- Step 3: Start and Configure MariaDB Enterprise Server
- Step 4: Test MariaDB Enterprise Server
- Step 1: Install MariaDB Enterprise Server
- Step 2: Start and Configure MariaDB Enterprise Server on Primary Server
- Step 3: Start and Configure MariaDB Enterprise Server on Replica Servers
- Step 4: Test MariaDB Enterprise Server
- Step 5: Install MariaDB MaxScale
- Step 6: Start and Configure MariaDB MaxScale
- Step 7: Test MariaDB MaxScale
- Single Node Topologies
- Community Server
- Community Server with ColumnStore
- Step 1: Prepare Systems for Enterprise ColumnStore Nodes
- Step 2: Install Enterprise ColumnStore
- Step 3: Start and Configure Enterprise ColumnStore
- Step 4: Test Enterprise ColumnStore
- Step 5: Bulk Import of Data
- Step 1: Prepare Systems for Enterprise ColumnStore Nodes
- Step 2: Install Enterprise ColumnStore
- Step 3: Start and Configure Enterprise ColumnStore
- Step 4: Test Enterprise ColumnStore
- Step 5: Bulk Import of Data
- Spider Storage Engine
- MariaDB Enterprise Spider Topologies
- Federated MariaDB Enterprise Spider Topology
- ODBC MariaDB Enterprise Spider Topology
- Sharded MariaDB Enterprise Spider Topology
- Spider Federated
- Step 1: Install Enterprise Spider
- Step 2: Configure Spider Node and Data Node
- Step 3: Test Spider Federated Topology
- Spider Sharded
- Step 1: Install Enterprise Spider
- Step 2: Configure Spider Node and Data Nodes
- Step 3: Test Spider Sharded Topology
- Server Constraints
- Server Constraints Overview
- AUTO_INCREMENT Constraints
- FOREIGN KEY Constraints
- NOT NULL Constraints
- PRIMARY KEY Constraints
- UNIQUE Constraints

Clients & Utilities

- Administrative Tools
- dbdeployer
- innochecksum
- mariadb-access
- mariadb-admin
- mariadb-conv
- mariadb-setpermission

- mariadb-show
- mariadb-plugin
- mariadb-report
- mariadb-find-rows
- mariadb-tzinfo-to-sql
- mariadb-waitpid
- my_print_defaults
- mariadb-embedded
- perror
- replace
- resolve_stack_dump

Aria Clients and Utilities
- aria_chk
- aria_pack
- aria_read_log

Backup, Restore and Import Clients
- mariadb-dump
- mariadb-hotcopy
- mariadb-import
- dbForge Studio

Deployment Tools
- mariadb-install-db
- mariadb-upgrade
- mariadb-secure-installation

Graphical and Enhanced Clients
- Adminer
- AdminNeo
- Beekeeper Studio
- SQL Diagnostic Manager & SQLyog
- Database Workbench
- dbForge Data Compare
- dbForge Data Generator
- dbForge Documenter
- dbForge Edge
- dbForge Fusion
- dbForge Query Builder
- dbForge Schema Compare
- dbForge Studio
- DbSchema
- DbVisualizer
- DeZign for Databases
- ERBuilder Data Modeler
- DBeaver
- OmniDB
- Sequel Pro
- HeidiSQL
- KS DB Merge Tools
- LibreOffice Base
- Luna Modeler
- mycli
- Navicat
- ocelotgui
- PgManage
- phpMyAdmin
- Querious
- SB Data Generator
- SQLPro Studio
- SQLyog
- TablePlus
- TOAD Edge
- Valentina Studio
- MariaDB Direct Query Adapter For Microsoft Power BI

Logging Tools
- mariadb-binlog
  - Using mariadb-binlog
  - mariadb-binlog Options
  - Annotate_rows_log_event
  - mysqlbinlog
- mariadb-dumpslow

mariadb Client
- mariadb Command-Line Client
- mysql Command-Line Client

Networking Tools
- resolveip

Table Tools
- mariadb-check
- mariadb-convert-table-format
- mariadb-fix-extensions

Testing Tools
- mariadb-slap
- mariadb-stress-test
- mariadb-test
  - mariadb-test Overview
  - Installing MinIO for Usage With mariadb-test-run
  - mariadb-test Auxiliary Files
  - mariadb-test-run.pl Options
  - New Features for mysqltest in MariaDB
  - Pausing mariadb-test-run.pl
  - The Debug Sync Facility

MyISAM Clients and Utilities
- Memory and Disk Use With myisamchk
- MyISAM Database Management using GUI Client
- myisam_ftdump
- myisamchk Table Information
- myisamchk
- myisamlog
- myisampack

Server & Client Software

Error Codes
- MariaDB Error Code Reference
- Operating System Error Codes
- MariaDB Error Codes 1000 to 1099
  - Error 1000: hashchk
  - Error 1001: isamchk
  - Error 1002: NO
  - Error 1003: YES
  - Error 1004: Can't create file
  - Error 1005: Can't create table
  - Error 1006: Can't create database
  - Error 1007: Can't create database, database exists
  - Error 1008: Can't drop database; database doesn't exist
  - Error 1009: Error dropping database (can't delete)
  - Error 1010: Error dropping database (can't rmdir)
  - Error 1011: Error on delete of
  - Error 1012: Can't read record in system table
  - Error 1013: Can't get status of
  - Error 1014: Can't get working directory
  - Error 1015: Can't lock file
  - Error 1016: Can't open file
  - Error 1017: Can't find file
  - Error 1018: Can't read dir of
  - Error 1019: Can't change dir to
  - Error 1020: Record has changed since last read in table
  - Error 1021: Disk full (%s); waiting for someone to free some space
  - Error 1022: Can't write; duplicate key in table
  - Error 1023: Error on close of
  - Error 1024: Error reading file
  - Error 1025: Error on rename of
  - Error 1026: Error writing file
  - Error 1027: is locked against change
  - Error 1028: Sort aborted
  - Error 1029: View doesn't exist for
  - Error 1030: Got error from storage engine
  - Error 1031: Table storage engine doesn't have this option
  - Error 1032: Can't find record in
  - Error 1033: Incorrect information in file
  - Error 1034: Incorrect key file for table; try to repair it
  - Error 1035: Old key file for table; repair it!
  - Error 1036: Table is read only
  - Error 1037: Out of memory; restart server and try again
  - Error 1038: Out of sort memory, consider increasing server sort buffer size
  - Error 1039: Unexpected EOF found when reading file
  - Error 1040: Too many connections
  - Error 1041: Out of memory
  - Error 1042: Can't get hostname for your address
  - Error 1043: Bad handshake
  - Error 1044: Access denied for user
  - Error 1045: Access denied for user (using password)
  - Error 1046: No database selected
  - Error 1047: Unknown command
  - Error 1048: Column cannot be null
  - Error 1049: Unknown database
  - Error 1050: Table already exists
  - Error 1051: Unknown table
  - Error 1052: Column is ambiguous
  - Error 1053: Server shutdown in progress
  - Error 1054: Unknown column
  - Error 1055: isn't in GROUP BY
  - Error 1056: Can't group on
  - Error 1057: Statement has sum functions and columns in same statement
  - Error 1058: Column count doesn't match value count
  - Error 1059: Identifier name is too long
  - Error 1060: Duplicate column name
  - Error 1061: Duplicate key name
  - Error 1062: Duplicate entry for key
  - Error 1063: Incorrect column specifier for column
  - Error 1064: near at line
  - Error 1065: Query was empty
  - Error 1066: Not unique table/alias
  - Error 1067: Invalid default value for
  - Error 1068: Multiple primary key defined
  - Error 1069: Too many keys specified; max keys allowed
  - Error 1070: Too many key parts specified; max parts allowed
  - Error 1071: Specified key was too long; max key length is
  - Error 1072: Key column doesn't exist in table
  - Error 1073: BLOB column can't be used in key specification with the used table type
  - Error 1074: Column length too big for column; use BLOB or TEXT instead
  - Error 1075: Incorrect table definition; there can be only one auto column and it must be defined as
  - Error 1076: ready for connections
  - Error 1077: Normal shutdown
  - Error 1078: Got signal. Aborting!
  - Error 1079: Shutdown complete
  - Error 1080: Forcing close of thread
  - Error 1081: Can't create IP socket
  - Error 1082: Table has no index like the one used in CREATE INDEX; recreate the table
  - Error 1083: Field separator argument is not what is expected; check the manual
  - Error 1084: You can't use fixed rowlength with BLOBs; please use 'fields terminated by'
  - Error 1085: The file must be in the database directory or be readable by all
  - Error 1086: File already exists
  - Error 1087: Records Deleted Skipped Warnings
  - Error 1088: Records Duplicates
  - Error 1089: Incorrect prefix key; the used key part isn't a string, the used length is longer than t
  - Error 1090: You can't delete all columns with ALTER TABLE; use DROP TABLE instead
  - Error 1091: Can't DROP; check that column/key exists
  - Error 1092: Records Duplicates Warnings
  - Error 1093: You can't specify target table for update in FROM clause
  - Error 1094: Unknown thread id
  - Error 1095: You are not owner of thread
  - Error 1096: No tables used
  - Error 1097: Too many strings for column and SET
  - Error 1098: Can't generate a unique log-filename

- Error 1099: Table was locked with a READ lock and can't be updated

MariaDB Error Codes 1100 to 1199

- Error 1100: Table was not locked with LOCK TABLES
- Error 1101: You should never see it
- Error 1102: Incorrect database name
- Error 1103: Incorrect table name
- Error 1104: The SELECT would examine more than MAX_JOIN_SIZE rows
- Error 1105: Unknown error
- Error 1106: Unknown procedure
- Error 1107: Incorrect parameter count to procedure
- Error 1108: Incorrect parameters to procedure
- Error 1109: Unknown table
- Error 1110: Column specified twice
- Error 1111: Invalid use of group function
- Error 1112: Table uses an extension that doesn't exist in this MariaDB version
- Error 1113: A table must have at least 1 column
- Error 1114: The table is full
- Error 1115: Unknown character set
- Error 1116: Too many tables; MariaDB can only use tables in a join
- Error 1117: Too many columns
- Error 1118: Row size too large
- Error 1119: Thread stack overrun
- Error 1120: Cross dependency found in OUTER JOIN; examine your ON conditions
- Error 1121: Table handler doesn't support NULL in given index
- Error 1122: Can't load function
- Error 1123: Can't initialize function
- Error 1124: No paths allowed for shared library
- Error 1125: Function already exists
- Error 1126: Can't open shared library
- Error 1127: Can't find symbol in library
- Error 1128: Function is not defined
- Error 1129: Host is blocked because of many connection errors
- Error 1130: Host is not allowed to connect to this MariaDB server
- Error 1131: You are using MariaDB as an anonymous user
- Error 1132: You must have privileges to update tables in the mysql database
- Error 1133: Can't find any matching row in the user table
- Error 1134: Rows matched Changed Warnings
- Error 1135: Can't create a new thread
- Error 1136: Column count doesn't match value count at row
- Error 1137: Can't reopen table
- Error 1138: Invalid use of NULL value
- Error 1139: Got error from regexp
- Error 1140: Mixing of GROUP columns with no GROUP columns
- Error 1141: There is no such grant defined for user on host
- Error 1142: command denied to user for table
- Error 1143: command denied to user for column in table
- Error 1144: Illegal GRANT/REVOKE command
- Error 1145: The host or user argument to GRANT is too long
- Error 1146: Table doesn't exist
- Error 1147: There is no such grant defined for user on host on table
- Error 1148: The used command is not allowed with this MariaDB version
- Error 1149: You have an error in your SQL syntax
- Error 1150: Delayed insert thread couldn't get requested lock for table
- Error 1151: Too many delayed threads in use
- Error 1152: Aborted connection to db user
- Error 1153: Got a packet bigger than 'max_allowed_packet' bytes
- Error 1154: Got a read error from the connection pipe
- Error 1155: Got an error from fcntl()
- Error 1156: Got packets out of order
- Error 1157: Couldn't uncompress communication packet
- Error 1158: Got an error reading communication packets
- Error 1159: Got timeout reading communication packets
- Error 1160: Got an error writing communication packets
- Error 1161: Got timeout writing communication packets
- Error 1162: Result string is longer than 'max_allowed_packet' bytes
- Error 1163: The used table type doesn't support BLOB/TEXT columns
- Error 1164: The used table type doesn't support AUTO_INCREMENT columns
- Error 1165: INSERT DELAYED can't be used with table because it is locked
- Error 1166: Incorrect column name
- Error 1167: The used storage engine can't index column
- Error 1168: Unable to open underlying table which is differently defined or of non-MyISAM type or do
- Error 1169: Can't write, because of unique constraint, to table
- Error 1170: BLOB/TEXT column used in key specification without a key length
- Error 1171: All parts of a PRIMARY KEY must be NOT NULL
- Error 1172: Result consisted of more than one row
- Error 1173: This table type requires a primary key
- Error 1174: This version of MariaDB is not compiled with RAID support
- Error 1175: You are using safe update mode and you tried to update a table without a WHERE that uses
- Error 1176: Key doesn't exist in table
- Error 1177: Can't open table
- Error 1178: The storage engine for the table doesn't support
- Error 1179: You are not allowed to execute this command in a transaction

- Error 1190: Net error writing to master
- Error 1191: Can't find FULLTEXT index matching the column list
- Error 1192: Can't execute the given command because you have active locked tables or an active trans
- Error 1193: Unknown system variable
- Error 1194: Table is marked as crashed and should be repaired
- Error 1195: Table is marked as crashed and last (automatic?) repair failed
- Error 1196: Some non-transactional changed tables couldn't be rolled back
- Error 1197: Multi-statement transaction required more than 'max_binlog_cache_size' bytes of storage
- Error 1198: This operation cannot be performed with a running slave; run STOP SLAVE first
- Error 1199: This operation requires a running slave; configure slave and do START SLAVE

MariaDB Error Codes 1200 to 1299

- Error 1200: The server is not configured as slave
- Error 1201: Could not initialize master info structure
- Error 1202: Could not create slave thread; check system resources
- Error 1203: User already has more than 'max_user_connections' active connections

Error 1204: You may only use constant expressions with SET
Error 1205: Lock wait timeout exceeded; try restarting transaction
Error 1206: The total number of locks exceeds the lock table size
Error 1207: Update locks cannot be acquired during a READ UNCOMMITTED transaction
Error 1208: DROP DATABASE not allowed while thread is holding global read lock
Error 1209: CREATE DATABASE not allowed while thread is holding global read lock
Error 1210: Incorrect arguments to
Error 1211: is not allowed to create new users
Error 1212: Incorrect table definition; all MERGE tables must be in the same database
Error 1213: Deadlock found when trying to get lock; try restarting transaction
Error 1214: The used table type doesn't support FULLTEXT indexes
Error 1215: Cannot add foreign key constraint
Error 1216: Cannot add or update a child row: a foreign key constraint fails
Error 1217: Cannot delete or update a parent row: a foreign key constraint fails
Error 1218: Error connecting to master
Error 1219: Error running query on master
Error 1220: Error when executing command
Error 1221: Incorrect usage of
Error 1222: The used SELECT statements have a different number of columns
Error 1223: Can't execute the query because you have a conflicting read lock
Error 1224: Mixing of transactional and non-transactional tables is disabled
Error 1225: Option used twice in statement
Error 1226: User has exceeded the resource
Error 1227: Access denied; you need (at least one of) the privilege(s) for this operation
Error 1228: Variable is a SESSION variable and can't be used with SET GLOBAL
Error 1229: Variable is a GLOBAL variable and should be set with SET GLOBAL
Error 1230: Variable doesn't have a default value
Error 1231: Variable can't be set to the value of
Error 1232: Incorrect argument type to variable
Error 1233: Variable can only be set, not read
Error 1234: Incorrect usage/placement
Error 1235: This version of MariaDB doesn't yet support
Error 1236: Got fatal error from master when reading data from binary log
Error 1237: Slave SQL thread ignored the query because of replicate-*-table rules
Error 1238: Variable is a
Error 1239: Incorrect foreign key definition
Error 1240: Key reference and table reference don't match
Error 1241: Operand should contain column(s)
Error 1242: Subquery returns more than 1 row
Error 1243: Unknown prepared statement handler given
Error 1244: Help database is corrupt or does not exist
Error 1245: Cyclic reference on subqueries
Error 1246: Converting column from to
Error 1247: Reference not supported
Error 1248: Every derived table must have its own alias
Error 1249: Select was reduced during optimization
Error 1250: Table from one of the SELECTs cannot be used
Error 1251: Client does not support authentication protocol requested by server
Error 1252: All parts of a SPATIAL index must be NOT NULL
Error 1253: COLLATION is not valid for CHARACTER SET
Error 1254: Slave is already running
Error 1255: Slave already has been stopped
Error 1256: Uncompressed data size too large
Error 1257: ZLIB: Not enough memory
Error 1258: ZLIB: Not enough room in the output buffer
Error 1259: ZLIB: Input data corrupted
Error 1260: Row was cut by GROUP_CONCAT()
Error 1261: Row doesn't contain data for all columns
Error 1262: Row was truncated; it contained more data than there were input columns
Error 1263: Column set to default value; NULL supplied to NOT NULL columnError 1263: Column set to d
Error 1264: Out of range value for column
Error 1265: Data truncated for column
Error 1266: Using storage engine for table
Error 1267: Illegal mix of collations for operation
Error 1268: Cannot drop one or more of the requested users
Error 1269: Can't revoke all privileges for one or more of the requested users
Error 1270: Illegal mix of collations for operation
Error 1271: Illegal mix of collations for operation
Error 1272: Variable is not a variable component (can't be used as XXXX.variable_name)
Error 1273: Unknown collation
Error 1274: SSL parameters in CHANGE MASTER are ignored because this MariaDB slave was compiled with
Error 1275: Server is running in --secure-auth mode, but has a password in the old format
Error 1276: Field or reference of SELECT was resolved in SELECT
Error 1277: Incorrect parameter or combination of parameters for START SLAVE UNTIL
Error 1278: It is recommended to use --skip-slave-start when doing step-by-step replication with STA
Error 1279: SQL thread is not to be started so UNTIL options are ignored
Error 1280: Incorrect index name
Error 1281: Incorrect catalog name
Error 1282: Query cache failed to set size; new query cache size is
Error 1283: Column cannot be part of FULLTEXT index
Error 1284: Unknown key cache
Error 1285: MariaDB is started in --skip-name-resolve mode
Error 1286: Unknown storage engine
Error 1287: is deprecated and will be removed in a future release. Please use instead
Error 1288: The target table of the is not updatable
Error 1289: The feature is disabled; you need MariaDB built with to have it working
Error 1290: The MariaDB server is running with the option so it cannot execute this statement
Error 1291: Column has duplicated value
Error 1292: Truncated incorrect value
Error 1293: Incorrect table definition; there can be only one TIMESTAMP column with CURRENT_TIMESTAM
Error 1294: Invalid ON UPDATE clause
Error 1295: This command is not supported in the prepared statement protocol yet
Error 1296: Got error from
Error 1297: Got temporary error from
Error 1298: Unknown or incorrect time zone
Error 1299: Invalid TIMESTAMP value in column at row

MariaDB Error Codes 1300 to 1399

Error 1300: Invalid character string
Error 1301: Result was larger than max_allowed_packet - truncated
Error 1302: Conflicting declarations

Error 1303: Can't create from within another stored routine
Error 1304: already exists

Error 1475: First character of the FIELDS TERMINATED string is ambiguous
Error 1476: The foreign server you are trying to create already exists
Error 1477: The foreign server name you are trying to reference does not exist. Data source error
Error 1478: Table storage engine does not support the create option
Error 1479: Syntax error: PARTITIONING requires definition of VALUES for each partition
Error 1480: Only PARTITIONING can use VALUES in partition definition
Error 1481: MAXVALUE can only be used in last partition definition
Error 1482: Subpartitions can only be hash partitions and by key
Error 1483: Must define subpartitions on all partitions if on one partition
Error 1484: Wrong number of partitions defined, mismatch with previous setting
Error 1485: Wrong number of subpartitions defined, mismatch with previous setting
Error 1486: Constant/Random expression in (sub)partitioning function is not allowed
Error 1487: Expression in RANGE/LIST VALUES must be constant
Error 1488: Field in list of fields for partition function not found in table
Error 1489: List of fields is only allowed in KEY partitions
Error 1490: The partition info in the frm file is not consistent with what can be written into the f
Error 1491: The function returns the wrong type
Error 1492: For partitions each partition must be defined
Error 1493: VALUES LESS THAN value must be strictly increasing for each partition
Error 1494: VALUES value must be of same type as partition function
Error 1495: Multiple definition of same constant in list partitioning
Error 1496: Partitioning can not be used stand-alone in query
Error 1497: The mix of handlers in the partitions is not allowed in this version of MariaDB
Error 1498: For the partitioned engine it is necessary to define all
Error 1499: Too many partitions (including subpartitions) were defined

MariaDB Error Codes 1500 to 1599

Error 1500: It is only possible to mix RANGE/LIST partitioning with HASH/KEY partitioning for subpar

Error 1501: Failed to create specific handler file

Error 1502: A BLOB field is not allowed in partition function

Error 1503: must include all columns in the table's partitioning function

Error 1504: Number of = 0 is not an allowed value

Error 1505: Partition management on a not partitioned table is not possible

Error 1506: Foreign key clause is not yet supported in conjunction with partitioning

Error 1507: Error in list of partitions to

Error 1508: Cannot remove all partitions, use DROP TABLE instead

Error 1509: COALESCE PARTITION can only be used on HASH/KEY partitions

Error 1510: REORGANIZE PARTITION can only be used to reorganize partitions not to change their numbe

Error 1511: REORGANIZE PARTITION without parameters can only be used on auto-partitioned tables

Error 1512: PARTITION can only be used on RANGE/LIST partitions

Error 1513: Trying to Add partition(s) with wrong number of subpartitions

Error 1514: At least one partition must be added

Error 1515: At least one partition must be coalesced

Error 1516: More partitions to reorganize than there are partitions

Error 1517: Duplicate partition name

Error 1518: It is not allowed to shut off binlog on this command

Error 1519: When reorganizing a set of partitions they must be in consecutive order

Error 1520: Reorganize of range partitions cannot change total ranges except for last partition

Error 1521: Partition function not supported in this version for this handler

Error 1522: Partition state cannot be defined from CREATE/ALTER TABLE

Error 1523: The handler only supports 32 bit integers in VALUES

Error 1524: Plugin is not loaded

Error 1525: Incorrect value

Error 1526: Table has no partition for value

Error 1527: It is not allowed to specify more than once

Error 1528: Failed to create

Error 1529: Failed to drop

Error 1530: The handler doesn't support autoextend of tablespaces

Error 1531: A size parameter was incorrectly specified, either number or on the form 10M

MariaDB Server Documentation

> **Note:**
>
> 📄 Read offline: mariadb-server.pdf (~6,200 pages, 80 MB). The PDF is a point-in-time snapshot; this site is always current.

See Quickstart Guides.

Get started quickly with MariaDB Server using these quickstart guides. Follow step-by-step instructions to install, configure, and begin using MariaDB for your projects.

See Server Usage.

Learn how to effectively use MariaDB Server. This section covers SQL statements, built-in functions, client utilities, and best practices for daily database operations.

See Server Management.

Effectively managing your MariaDB Server is key to ensuring its reliability, performance, and security. This section serves as your central hub for all aspects of MariaDB Server management.

See Security.

Secure your MariaDB Server. This section provides comprehensive guidance on user management, encryption, authentication, auditing, and other crucial security measures.

See Architecture.

Understand MariaDB Server's architecture. Explore its components, storage engines, and how they interact to provide a high-performance, reliable database solution.

See Clients & Utilities.

Discover MariaDB Server's clients and utilities. This section guides you through tools for connecting, managing, and interacting with your database, from command-line clients to graphical interfaces.

See HA & Performance.

Optimize MariaDB Server for high availability and performance. Learn about replication, clustering, load balancing, and configuration tuning for robust and efficient database solutions.

See Reference.

Access the comprehensive MariaDB Server reference. Find detailed documentation on SQL syntax, data types, functions, system variables, and other technical specifications.

Quickstart Guides

See Installing MariaDB Server Guide.

Official MariaDB Server install guide: Linux apt/dnf/yum commands, mariadb-secure-installation setup, systemctl status/start checks, Windows .msi installer.

See Adding & Changing Data Guide.

This guide provides a walkthrough of the INSERT, UPDATE, and DELETE statements, demonstrating how to add, modify, and remove data in tables.

See Essential Queries Guide.

Learn how to perform essential SQL operations such as creating tables, inserting data, and using aggregate functions like MAX, MIN, and AVG.

See Basics Guide.

Complete MariaDB basics guide: connect with mariadb -u/-p/-h, CREATE DATABASE/USE, CREATE TABLE with AUTO_INCREMENT, INSERT/SELECT/UPDATE/DELETE commands.

See Altering Tables Guide.

Learn how to modify existing table structures using the ALTER TABLE statement, including adding columns, changing types, and managing indexes.

See Connecting to MariaDB Guide.

This guide details how to connect to a MariaDB server using the command-line client, covering options for host, user, password, and protocol.

See Troubleshooting Connection Issues Guide.

Diagnose and fix common MariaDB Server connection problems, such as “Can’t connect to local server” and access-denied errors, with step-by-step troubleshooting.

See Doing Time Guide.

Understand how to work with date and time values in MariaDB, including data types like DATETIME and TIMESTAMP, and useful temporal functions.

See Importing Data Guide.

Learn how to efficiently import data into MariaDB tables from external files using the LOAD DATA INFILE statement.

See Essentials of an Index Guide.

This guide provides a conceptual overview of database indexes, explaining their purpose, different types, and when to use them for optimization.

See Getting Started with Indexes Guide.

Definitive MariaDB indexes guide: PRIMARY KEY, UNIQUE INDEX, INDEX, FULLTEXT types, CREATE/ALTER TABLE syntax, CREATE INDEX, SHOW INDEX, and EXPLAIN.

See Joining Tables with JOIN Clauses.

This guide introduces the different types of JOINs (INNER, LEFT, RIGHT, CROSS) and demonstrates how to combine data from multiple tables.

See Advanced Joins.

Explore complex join scenarios. This guide covers filtering joined data with WHERE clauses, handling dates, and aggregating results from multiple tables for deeper analysis.

See Configuring MariaDB for Remote Client Access Guide.

Configure MariaDB Server to accept remote connections by setting bind-address, granting privileges for remote users, and opening the right firewall rules.

See Getting Data Guide.

This guide explains the SELECT statement in detail, covering how to retrieve, filter, limit, and sort data from your MariaDB database.

See Basic SQL Statements Guide.

A quick reference for core SQL statements including DDL (CREATE, DROP), DML (INSERT, UPDATE, DELETE), and TCL (COMMIT, ROLLBACK) commands.

See Basic SQL Debugging Guide.

This guide offers conventions and practical tips for designing SQL queries that are easier to read, understand, and debug.

See MariaDB String Functions Guide.

This guide goes through several built-in string functions in MariaDB, grouping them by similar features, and providing examples of how they might be used.

See Restoring Data from Dump Files Guide.

Restore MariaDB data from mariadb-dump backup files using the mariadb client, including how to selectively restore a single table.

See Changing Times in MariaDB.

This guide explores MariaDB functions for performing calculations and modifications on date and time values, like DATE_ADD and DATE_SUB.

See System & Status Variables Guide.

This guide indicates where the various system and status variables of MariaDB Server are found.

See Making Backups with mariadb-dump Guide.

Create logical backups of MariaDB databases with the mariadb-dump utility, covering how to back up all databases, specific databases, or individual tables.

See A MariaDB Primer Guide.

A beginner-friendly primer on using the mariadb command-line client to log in, create databases, and execute basic SQL commands.

See Creating & Using Views Guide.

Discover how to create and use views to simplify complex queries, restrict data access, and present a specific perspective of your data.

See Database Applications.

This section offers advice on writing and maintaining applications that use databases, covering schema design, code practices, and testing.

Installing MariaDB Server Guide

This guide provides step-by-step instructions for installing MariaDB Server on various operating systems, including package updates and security settings.

For Linux (Ubuntu/Debian/Red Hat-based distributions)

The most common way to install MariaDB on Linux is through your system's package manager.

Steps:

1. Update Package List:

   Before installing, it's a good practice to update your package index.

   - For Debian/Ubuntu:Bash

     ```
     sudo apt update
     ```

   - For Red Hat/CentOS/Fedora:Bash

     ```
     sudo yum update # For older systems
     sudo dnf update # For newer systems
     ```

2. Install MariaDB Server:

   Install the MariaDB server and client packages.

   - For Debian/Ubuntu:Bash

     ```
     sudo apt install mariadb-server mariadb-client galera-4
     ```

   - For Red Hat/CentOS/Fedora:Bash

     ```
     sudo dnf install mariadb mariadb-server
     ```

3. Secure the Installation:

   After installation, run the security script to set a root password, remove anonymous users, and disable remote root login.

   ```
   sudo mariadb-secure-installation
   ```

   Follow the prompts to configure your security settings.

4. Start and Verify the Service:

   MariaDB typically starts automatically after installation. You can check its status and manually start it if needed.

   - Check status:

     ```
     sudo systemctl status mariadb
     ```

   - Start service (if not running):Bash

     ```
     sudo systemctl start mariadb
     ```

   - Verify installation by connecting as root:Bash

     ```
     mariadb -u root -p
     ```

Enter the root password you set during the secure installation.

For Windows

For Windows, MariaDB provides an `.msi` installer for a straightforward graphical installation.

Steps:

1. Download MariaDB:

   Visit the MariaDB downloads page to get the latest `.msi` installer.

2. Run the Installer:

   Double-click the downloaded `.msi` file to start the installation wizard.

3. Follow On-Screen Instructions:

   The installer will guide you through the process, including:

   - Accepting the end-user license agreement.
   - Selecting features and the installation directory.
   - Setting a password for the `root` user.
   - Configuring MariaDB as a service and setting the port (default is 3306).
   - Optionally, enabling UTF8 as the default server character set.

Important Notes:

- **Firewall:** Ensure your firewall is configured to allow connections to MariaDB on the appropriate port (default 3306) if you need remote access.
- **Root Password:** Always set a strong root password during the secure installation step.
- **Further Configuration:** For production environments, you may need to adjust further settings in the MariaDB configuration files (e.g., `my.cnf` on Linux).

Adding & Changing Data Guide

This guide explains how to add new data and modify existing data in MariaDB using `INSERT`, `REPLACE`, and `UPDATE` statements. Learn about various options for handling duplicates, managing statement priorities, inserting data from other tables, and performing conditional updates.

Adding Data with `INSERT`

The `INSERT` statement is used to add new rows to a table.

Basic Syntax:

If providing values for all columns in their defined order:

```
INSERT table1 VALUES('value1','value2','value3');
```

The number of values must match the number of columns in `table1`.

Specifying Columns:

It's good practice to specify the columns you are inserting data into, which also allows you to insert columns in any order or omit columns that have default values or allow NULL.

```
INSERT INTO table1 (col3, col1) VALUES('value_for_col3', 'value_for_col1');
```

- The `INTO` keyword is optional but commonly used for readability.
- If a column is not listed and is an `AUTO_INCREMENT` key, its value will be generated. For other omitted columns, their `DEFAULT` value will be used, or `NULL` if allowed. You can explicitly insert a default value using the `DEFAULT` keyword in the `VALUES` list for a specific column.

Multiple Row Inserts:

Insert multiple rows in a single statement for efficiency:

```
INSERT INTO table2 (id_col, data_col1, data_col2) VALUES
  ('id1', 'text_a', 'text_b'),
  ('id2', 'text_c', 'text_d'),
  ('id3', 'text_e', 'text_f');
```

The `VALUES` keyword is used only once, with each row's values enclosed in parentheses and separated by commas.

Handling Duplicates with INSERT IGNORE:

If you attempt to insert a row that would cause a duplicate value in a PRIMARY KEY or UNIQUE index, an error normally occurs, and the row (and potentially subsequent rows in a multi-row insert) might not be inserted.

Using IGNORE tells MariaDB to discard the duplicate row(s) and continue inserting any other valid rows without generating an error.

```
INSERT IGNORE INTO table2 (unique_id_col, data_col) VALUES
  ('id1', 'some_data'),        -- Will be inserted if new
  ('id2', 'other_data'),       -- Will be inserted if new
  ('id1', 'duplicate_data');  -- Will be ignored if 'id1' already exists or was just inserted
```

Managing `INSERT` Priority and Behavior

LOW_PRIORITY:

An INSERT statement normally takes priority over SELECT statements, potentially locking the table and making other clients wait. LOW_PRIORITY makes the INSERT wait until no other clients are reading from the table.

```
INSERT LOW_PRIORITY INTO table1 VALUES('value1','value2','value3');
```

- Once the `LOW_PRIORITY` insert begins, it will lock the table as usual. New read requests that arrive while it's waiting will be processed before it.

DELAYED:

`INSERT DELAYED` lets the server queue the insert request and return control to the client immediately; the rows are written when the table is not in use, and inserts from many clients are batched together.

```
INSERT DELAYED INTO table1 VALUES('value1','value2','value3');
```

- `DELAYED` works only with non-transactional storage engines — `MyISAM`, `MEMORY`, `ARCHIVE`, `BLACKHOLE`, non-transactional `Aria`, and `OQGRAPH`. Using it with another engine returns an error.
- It is controlled by the `max_delayed_threads` system variable; setting that to `0` disables `DELAYED`.

- Because control returns before the rows are written, there is no confirmation of success, and queued rows held in memory are lost if the server stops before they are written. See INSERT DELAYED for the full list of limitations.

Inserting Data from Another Table (`INSERT...SELECT`)

You can insert rows into a table based on data retrieved from another table (or tables) using `INSERT ... SELECT`.

```
INSERT INTO softball_team (last_name, first_name, telephone)
  SELECT name_last, name_first, tel_home
  FROM company_database.employees
  WHERE is_on_softball_team = 'Y';
```

- The columns in the `INSERT INTO softball_team (...)` list must correspond in number and general data type compatibility to the columns in the `SELECT` list.
- `INSERT...SELECT` statements generally cannot operate on the exact same table as both the target and the source directly without mechanisms like temporary tables or certain subquery structures.

Replacing Data with `REPLACE`

The `REPLACE` statement works like `INSERT`, but if a new row has the same value as an existing row for a `PRIMARY KEY` or a `UNIQUE` index, the existing row is deleted before the new row is inserted. If no such conflict exists, it acts like a normal `INSERT`.

```
REPLACE LOW_PRIORITY INTO table2 (id_col, data_col1, data_col2) VALUES
  ('id1', 'new_text_a', 'new_text_b'), -- If 'id1' exists, old row is deleted, this is inserted
  ('id2', 'new_text_c', 'new_text_d'), -- If 'id2' doesn't exist, this is inserted
  ('id3', 'new_text_e', 'new_text_f');
```

- Flags like `LOW_PRIORITY` work similarly to `INSERT`.
- `REPLACE` also supports the `REPLACE ... SELECT` syntax.
- Because `REPLACE` performs a delete then an insert, any columns in the table not specified in the `REPLACE` statement will receive their default values for the newly inserted row, not values from the old row.

Modifying Data with `UPDATE`

Use the `UPDATE` statement to change data in existing rows.

Basic Syntax:

```
UPDATE table3
SET col1 = 'new_value_a', col2 = 'new_value_b'
WHERE id_column < 100;
```

- The `SET` clause specifies which columns to modify and their new values.
- The `WHERE` clause is crucial; it determines which rows are updated. **Without a `WHERE` clause, all rows in the table will be updated.**
- `LOW_PRIORITY` and `IGNORE` (to ignore errors like unique key violations during update, allowing other valid row updates to proceed) can also be used with `UPDATE`.

Using Current Column Values in an Update:

You can use a column's current value in the calculation for its new value.

```
UPDATE table5
SET event_date = DATE_ADD(event_date, INTERVAL 1 DAY)
WHERE DAYOFWEEK(event_date) = 1; -- Example: Add 1 day if event_date is a Sunday
```

ORDER BY and LIMIT with UPDATE:

You can control the order in which rows are updated and limit the number of rows affected (for single-table updates).

```
UPDATE LOW_PRIORITY table3
SET col1 = 'updated_text_a', col2 = 'updated_text_b'
WHERE status_column = 'pending'
ORDER BY creation_date DESC
LIMIT 10;
```

This updates the 10 most recently created ‘pending’ rows.

Multi-Table UPDATE:

You can update rows in one table based on values from another table by joining them.

```
UPDATE products p
JOIN stock_levels s ON p.product_id = s.product_id
SET p.stock_count = s.current_stock
WHERE s.warehouse_id = 'WHA';
```

- Here, `products.stock_count` is updated using values from `stock_levels`.
- `ORDER BY` and `LIMIT` are generally not allowed with multi-table `UPDATE` statements in this direct join form.

Conditional Inserts or Updates (`INSERT ... ON DUPLICATE KEY UPDATE`)

This powerful feature allows you to `INSERT ... ON DUPLICATE KEY UPDATE` a new row, but if a duplicate key (Primary or Unique) conflict occurs, it performs an `UPDATE` on the existing row instead.

```
INSERT INTO table1 (id, col1, col2, status_column)
VALUES ('1012', 'some_text', 'other_text', 'new')
ON DUPLICATE KEY UPDATE status_column = 'old', col2 = VALUES(col2);
```

- If `id` ‘1012’ does not exist, the row is inserted with `status_column = 'new'`.
- If `id` ‘1012’ already exists, the existing row is updated: `status_column` is set to ‘old’, and `col2` is updated with the value that *would have been inserted* for `col2` (using `VALUES(col2)`).
- The `IGNORE` keyword can be used with `INSERT ... ON DUPLICATE KEY UPDATE` to ignore errors that might occur during the `UPDATE` part if the update itself causes a problem (though this is less common). If `IGNORE` is used with `INSERT` and `ON DUPLICATE KEY UPDATE` is also present, `IGNORE` only applies to the `INSERT` part, not the `UPDATE` part.

Further Data Modification Methods

Beyond these SQL statements, MariaDB offers bulk methods for adding data, such as:

- `LOAD DATA INFILE`: For importing data from text files.
- `mariadb-import` utility: A command-line tool that uses `LOAD DATA INFILE`. These are covered in the Importing Data Guide.

This page is licensed: CC BY-SA / Gnu FDL

Essential Queries Guide

The Essential Queries Guide offers a concise collection of commonly-used SQL queries. It’s designed to help developers and database administrators quickly find syntax and examples for typical database operations, from table creation and data insertion to effective data retrieval and manipulation.

Creating a Table

To create new tables:

```
CREATE TABLE t1 ( a INT );
```

```
CREATE TABLE t2 ( b INT );
```

```
CREATE TABLE student_tests (
 name CHAR(10), test CHAR(10),
 score TINYINT, test_date DATE
);
```

For more details, see the official CREATE TABLE documentation.

Inserting Records

To add data into your tables:

```
INSERT INTO t1 VALUES (1), (2), (3);
```

```
INSERT INTO t2 VALUES (2), (4);
```

```
INSERT INTO student_tests
 (name, test, score, test_date) VALUES
 ('Chun', 'SQL', 75, '2012-11-05'),
 ('Chun', 'Tuning', 73, '2013-06-14'),
 ('Esben', 'SQL', 43, '2014-02-11'),
 ('Esben', 'Tuning', 31, '2014-02-09'),
 ('Kaolin', 'SQL', 56, '2014-01-01'),
 ('Kaolin', 'Tuning', 88, '2013-12-29'),
 ('Tatiana', 'SQL', 87, '2012-04-28'),
 ('Tatiana', 'Tuning', 83, '2013-09-30');
```

For more information, see INSERT.

Using AUTO_INCREMENT

The `AUTO_INCREMENT` attribute automatically generates a unique identity for new rows.

Create a table with an `AUTO_INCREMENT` column:

```
CREATE TABLE student_details (
 id INT NOT NULL AUTO_INCREMENT, name CHAR(10),
 date_of_birth DATE, PRIMARY KEY (id)
);
```

When inserting, omit the `id` field; it will be automatically generated:

```
INSERT INTO student_details (name,date_of_birth) VALUES
 ('Chun', '1993-12-31'),
 ('Esben','1946-01-01'),
 ('Kaolin','1996-07-16'),
 ('Tatiana', '1988-04-13');
```

Verify the inserted records:

```
SELECT * FROM student_details;
```

```
+----+---------+---------------+
| id | name    | date_of_birth |
+----+---------+---------------+
|  1 | Chun    | 1993-12-31    |
|  2 | Esben   | 1946-01-01    |
|  3 | Kaolin  | 1996-07-16    |
|  4 | Tatiana | 1988-04-13    |
+----+---------+---------------+
```

For more details, see the AUTO_INCREMENT documentation.

Querying from Two Tables on a Common Value (JOIN)

To combine rows from two tables based on a related column:

```
SELECT * FROM t1 INNER JOIN t2 ON t1.a = t2.b;
```

This type of query is a join. For more details, consult the documentation on JOINS.

Finding the Maximum Value

To find the maximum value in a column:

```
SELECT MAX(a) FROM t1;
```

```
+--------+
| MAX(a) |
+--------+
|      3 |
+--------+
```

See the MAX() function documentation. For a grouped example, refer to *Finding the Maximum Value and Grouping the Results* below.

Finding the Minimum Value

To find the minimum value in a column:

```
SELECT MIN(a) FROM t1;
```

```
+--------+
| MIN(a) |
+--------+
|      1 |
+--------+
```

See the MIN() function documentation.

Finding the Average Value

To calculate the average value of a column:

```
SELECT AVG(a) FROM t1;
```

```
+--------+
| AVG(a) |
+--------+
| 2.0000 |
+--------+
```

See the AVG() function documentation.

Finding the Maximum Value and Grouping the Results

To find the maximum value within groups:

```
SELECT name, MAX(score) FROM student_tests GROUP BY name;
```

```
+---------+------------+
| name    | MAX(score) |
+---------+------------+
| Chun    |         75 |
| Esben   |         43 |
| Kaolin  |         88 |
| Tatiana |         87 |
+---------+------------+
```

Further details are available in the MAX() function documentation.

Ordering Results

To sort your query results (e.g., in descending order):

```
SELECT name, test, score FROM student_tests
 ORDER BY score DESC; -- Use ASC for ascending order
```

```
+---------+--------+-------+
| name    | test   | score |
+---------+--------+-------+
| Kaolin  | Tuning |    88 |
| Tatiana | SQL    |    87 |
| Tatiana | Tuning |    83 |
| Chun    | SQL    |    75 |
| Chun    | Tuning |    73 |
| Kaolin  | SQL    |    56 |
| Esben   | SQL    |    43 |
| Esben   | Tuning |    31 |
+---------+--------+-------+
```

For more options, see the ORDER BY documentation.

Finding the Row with the Minimum of a Particular Column

To find the entire row containing the minimum value of a specific column across all records:

```
SELECT name, test, score FROM student_tests
 WHERE score = (SELECT MIN(score) FROM student_tests);
```

```
+-------+--------+-------+
| name  | test   | score |
+-------+--------+-------+
| Esben | Tuning |    31 |
+-------+--------+-------+
```

Finding Rows with the Maximum Value of a Column by Group

To retrieve the full record for the maximum value within each group (e.g., highest score per student):

```
SELECT name, test, score FROM student_tests st1
 WHERE score = (SELECT MAX(st2.score) FROM student_tests st2 WHERE st1.name = st2.name);
```

```
+---------+--------+-------+
| name    | test   | score |
+---------+--------+-------+
| Chun    | SQL    |    75 |
| Esben   | SQL    |    43 |
| Kaolin  | Tuning |    88 |
| Tatiana | SQL    |    87 |
+---------+--------+-------+
```

Calculating Age

Use the `TIMESTAMPDIFF` function to calculate age from a birth date.

To see the current date (optional, for reference):

```
SELECT CURDATE() AS today;
```

```
+------------+
| today      |
+------------+
| 2014-02-17 | -- Example output; actual date will vary
+------------+
```

To calculate age as of a specific date (e.g., '2014-08-02'):

```
SELECT name, date_of_birth, TIMESTAMPDIFF(YEAR, date_of_birth, '2014-08-02') AS age
  FROM student_details;
```

```
+---------+---------------+------+
| name    | date_of_birth | age  |
+---------+---------------+------+
| Chun    | 1993-12-31    |   20 |
| Esben   | 1946-01-01    |   68 |
| Kaolin  | 1996-07-16    |   18 |
| Tatiana | 1988-04-13    |   26 |
+---------+---------------+------+
```

To calculate current age, replace the specific date string (e.g., '2014-08-02') with CURDATE().

See the TIMESTAMPDIFF() documentation for more.

Using User-Defined Variables

User-defined variablescan store values for use in subsequent queries within the same session.

Example: Set a variable for the average score and use it to filter results.

```
SELECT @avg_score := AVG(score) FROM student_tests;
```

```
+-------------------------+
| @avg_score:= AVG(score) |
+-------------------------+
|            67.000000000 |
+-------------------------+
```

```
SELECT * FROM student_tests WHERE score > @avg_score;
```

```
+---------+--------+-------+------------+
| name    | test   | score | test_date  |
+---------+--------+-------+------------+
| Chun    | SQL    |    75 | 2012-11-05 |
| Chun    | Tuning |    73 | 2013-06-14 |
| Kaolin  | Tuning |    88 | 2013-12-29 |
| Tatiana | SQL    |    87 | 2012-04-28 |
| Tatiana | Tuning |    83 | 2013-09-30 |
+---------+--------+-------+------------+
```

Example: Add an incremental counter to a result set.

```
SET @count = 0;
```

```
SELECT @count := @count + 1 AS counter, name, date_of_birth FROM student_details;
```

```
+---------+---------+---------------+
| counter | name    | date_of_birth |
+---------+---------+---------------+
|       1 | Chun    | 1993-12-31    |
|       2 | Esben   | 1946-01-01    |
|       3 | Kaolin  | 1996-07-16    |
|       4 | Tatiana | 1988-04-13    |
+---------+---------+---------------+
```

See User-defined Variables for more.

View Tables in Order of Size

To list all tables in the current database, ordered by their size (data + index) in megabytes:

```
SELECT table_schema AS `DB`, table_name AS `TABLE`,
  ROUND(((data_length + index_length) / 1024 / 1024), 2) `Size (MB)`
  FROM information_schema.TABLES
  WHERE table_schema = DATABASE() -- This clause restricts results to the current database
  ORDER BY (data_length + index_length) DESC;
```

```
+--------------------+---------------------------------------+-----------+
| DB                 | Table                                 | Size (MB) | -- Example Output
+--------------------+---------------------------------------+-----------+
| your_db_name       | some_large_table                      |      7.05 |
| your_db_name       | another_table                         |      6.59 |
...
+--------------------+---------------------------------------+-----------+
```

Removing Duplicates

To remove duplicate rows based on specific column values, while keeping one instance (e.g., the instance with the highest `id`).

This example assumes `id` is a unique primary key and duplicates are identified by the values in column `f1`. It keeps the row with the maximum `id` for each distinct `f1` value.

Setup sample table and data:

```
CREATE TABLE t (id INT, f1 VARCHAR(2));
```

```
INSERT INTO t VALUES (1,'a'), (2,'a'), (3,'b'), (4,'a');
```

To delete duplicate rows, keeping the one with the highest `id` for each group of `f1` values:

```
DELETE t_del FROM t AS t_del
INNER JOIN (
    SELECT f1, MAX(id) AS max_id
    FROM t
    GROUP BY f1
    HAVING COUNT(*) > 1 -- Identify groups with actual duplicates
) AS t_keep ON t_del.f1 = t_keep.f1 AND t_del.id < t_keep.max_id;
```

This query targets rows for deletion (`t_del`) where their `f1` value matches an `f1` in a subquery (`t_keep`) that has duplicates, and their `id` is less than the maximum `id` found for that `f1` group.

Verify results after deletion:

```
SELECT * FROM t;
```

```
+------+------+
| id   | f1   |
+------+------+
|    3 | b    |
|    4 | a    |
+------+------+
```

Basics Guide

The quickstart guide walks you through connecting to a MariaDB server, creating your initial database and table structures, and performing fundamental data operations. It's designed for new users or anyone needing a quick refresher on essential MariaDB commands and basic syntax.

Connecting to MariaDB Server

To interact with the MariaDB server, use a client program. The default command-line client is `mariadb` .

Connect to MariaDB in monitor mode from the Linux command-line:

```
mariadb -u root -p -h localhost
```

Common options:

- `-u username` : Specifies the MariaDB user (e.g., `root`). This is not the OS user.
- `-p` : Prompts for the password. If no password is set, press [Enter].
- `-h hostname_or_IP` : Specifies the server's hostname or IP address if the client is on a different machine than the server. Often not needed if connecting locally.

If logged into Linux as `root` , you might only need:

```
mariadb -p
```

To exit the `mariadb` monitor, type `quit` or `exit` and press [Enter].

Creating a Database Structure

First, create and select a database.

```
CREATE DATABASE bookstore;
USE bookstore;
```

This creates a database named `bookstore` and sets it as the default for subsequent operations.

Next, create tables to hold data.

```
CREATE TABLE books (
    isbn CHAR(20) PRIMARY KEY,
    title VARCHAR(50),
    author_id INT,
    publisher_id INT,
    year_pub CHAR(4),
    description TEXT
);
```

This statement creates a `books` table with six columns:

- `isbn`: `CHAR(20)`, the primary key for unique identification.
- `title`: `VARCHAR(50)`, a variable-width string for the book title.
- `author_id`, `publisher_id`: `INT`, for storing numeric IDs.
- `year_pub`: `CHAR(4)`, a fixed-width string for the publication year.
- `description`: `TEXT`, for longer descriptive text (up to 65,535 bytes).

To view the structure of a created table:

```
DESCRIBE books;
```

```
+--------------+-------------+------+-----+---------+-------+
| Field        | Type        | Null | Key | Default | Extra |
+--------------+-------------+------+-----+---------+-------+
| isbn         | char(20)    | NO   | PRI | NULL    |       |
| title        | varchar(50) | YES  |     | NULL    |       |
| author_id    | int(11)     | YES  |     | NULL    |       |
| publisher_id | int(11)     | YES  |     | NULL    |       |
| year_pub     | char(4)     | YES  |     | NULL    |       |
| description  | text        | YES  |     | NULL    |       |
+--------------+-------------+------+-----+---------+-------+
```

To modify an existing table, use the `ALTER TABLE` statement (see ALTER TABLE documentation). To delete a table and all its data (irreversibly), use `DROP TABLE table_name;` (see DROP TABLE documentation).

Example of another table, `authors`, using `AUTO_INCREMENT` for the primary key:

```
CREATE TABLE authors (
    author_id INT AUTO_INCREMENT PRIMARY KEY,
    name_last VARCHAR(50),
    name_first VARCHAR(50),
    country VARCHAR(50)
);
```

The `author_id` will automatically generate a unique number for each new author.

SQL Syntax Notes

- SQL statements typically end with a semicolon (`;`) or `\G`.
- Statements can span multiple lines; execution occurs after the terminating character and [Enter].
- To cancel a partially typed statement in the `mariadb` client, enter `\c` and press [Enter].
- SQL reserved words (e.g., `CREATE`, `SELECT`) are often written in uppercase for readability but are case-insensitive in MariaDB.
- Database and table names are case-sensitive on Linux systems (as they map to directories and files) but generally not on Windows. Column names are case-insensitive.

- Using lowercase for table and column names is a common convention.

Entering Data

Use the `INSERT` statement (see INSERT documentation) to add new rows to a table.

```
INSERT INTO authors (name_last, name_first, country)
VALUES('Kafka', 'Franz', 'Czech Republic');
```

Since `author_id` in the `authors` table is `AUTO_INCREMENT` (see AUTO_INCREMENT documentation), its value is assigned automatically. If not all columns are being supplied with data, the column names must be listed, followed by their corresponding values in the `VALUES` clause.

To insert data for a book, referencing `author_id` `1` (assuming Kafka's `author_id` became `1`):

```
INSERT INTO books (title, author_id, isbn, year_pub)
VALUES('The Castle', '1', '0805211063', '1998');
```

Multiple rows can be inserted with a single `INSERT` statement:

```
INSERT INTO books (title, author_id, isbn, year_pub)
VALUES('The Trial', '1', '0805210407', '1995'),
      ('The Metamorphosis', '1', '0553213695', '1995'),
      ('America', '1', '0805210644', '1995');
```

Retrieving Data

Use the SELECT statement (see SELECT documentation) to query data from tables.

To retrieve all book titles:

```
SELECT title FROM books;
```

To limit the number of rows returned (e.g., to 5) using `LIMIT` (see LIMIT documentation):

```
SELECT title FROM books LIMIT 5;
```

To retrieve data from multiple tables, use a `JOIN` (see JOIN documentation). This example lists book titles and author last names by joining `books` and `authors` on their common `author_id` column:

```
SELECT title, name_last
FROM books
JOIN authors USING (author_id);
```

To filter results, use the `WHERE` clause. This example finds books by 'Kafka' and renames the `title` column[1] in the output to 'Kafka Books' using `AS` (an alias):

```
SELECT title AS 'Kafka Books'
FROM books
JOIN authors USING (author_id)
WHERE name_last = 'Kafka';
```

```
+-------------------+
| Kafka Books       |
+-------------------+
| The Castle        |
| The Trial         |
| The Metamorphosis |
| America           |
+-------------------+
```

Changing & Deleting Data

To modify existing data, use the `UPDATE` statement (see UPDATE documentation). Always use a `WHERE` clause to specify which rows to update.

```
UPDATE books
SET title = 'Amerika'
WHERE isbn = '0805210644';
```

This changes the `title` for the book with the specified `isbn`. Multiple columns can be updated by separating `column = value` assignments with commas within the `SET` clause.

To remove rows from a table, use the `DELETE` statement (see DELETE documentation). Use `WHERE` to specify which rows to delete.

```
DELETE FROM books
WHERE author_id = '2034'; -- Assuming '2034' is the author_id to be deleted
```

This deletes all books associated with `author_id` ‘2034’.

Altering Tables Guide

This guide provides essential instructions for modifying existing table structures. Learn how to add, drop, and change columns, manage indexes and default values, and rename tables, along with key precautions for these operations when working with your database.

Before You Begin: Backup Your Tables

Before making any structural changes to a table, especially if it contains data, **always create a backup**. The `mariadb-dump` utility is a common and effective tool for this.

Example: Backing up a single table

Suppose you have a database db1 and a table clients. Its initial structure is:

```
DESCRIBE clients;
```

```
+-------------+-------------+------+-----+---------+-------+
| Field       | Type        | Null | Key | Default | Extra |
+-------------+-------------+------+-----+---------+-------+
| cust_id     | int(11)     |      | PRI | 0       |       |
| name        | varchar(25) | YES  |     | NULL    |       |
| address     | varchar(25) | YES  |     | NULL    |       |
| city        | varchar(25) | YES  |     | NULL    |       |
| state       | char(2)     | YES  |     | NULL    |       |
| zip         | varchar(10) | YES  |     | NULL    |       |
| client_type | varchar(4)  | YES  |     | NULL    |       |
+-------------+-------------+------+-----+---------+-------+
```

To back up the `clients` table from the command-line:

```
mariadb-dump --user='your_username' --password='your_password' --add-locks db1 clients > clients.sql
```

- Replace `'your_username'` and `'your_password'` with your actual MariaDB credentials.
- `--add-locks`: Locks the table during the backup and unlocks it afterward.
- `db1 clients`: Specifies the database and then the table.
- `> clients.sql`: Redirects the output to a file named `clients.sql`.

Restoring from a backup

If you need to restore the table:

```
mariadb --user='your_username' --password='your_password' db1 < clients.sql
```

This command uses the `mariadb` client to execute the SQL in `clients.sql`, which will typically drop the existing table (if it exists) and recreate it from the backup. Ensure no critical data has been added to the live table since the backup if you intend to overwrite it.

For the examples that follow, we'll assume structural changes are being made, sometimes on an empty table for simplicity, but the backup step is always recommended for tables with data.

Adding Columns

Use the `ALTER TABLE` statement with the `ADD COLUMN` clause.

Add a column to the end of the table:

To add a status column with a fixed width of two characters:

```
ALTER TABLE clients
ADD COLUMN status CHAR(2);
```

Add a column after a specific existing column:

To add address2 (varchar 25) after the address column:

```
ALTER TABLE clients
ADD COLUMN address2 VARCHAR(25) AFTER address;
```

Add a column to the beginning of the table:

```
ALTER TABLE clients
ADD COLUMN new_first_column VARCHAR(50) FIRST;
```

(Assuming `new_first_column` is the one to be added at the beginning).

After additions, the table structure might look like (excluding `new_first_column` for consistency with original example flow):

```
DESCRIBE clients;
```

```
+-------------+-------------+------+-----+---------+-------+
| Field       | Type        | Null | Key | Default | Extra |
+-------------+-------------+------+-----+---------+-------+
| cust_id     | int(11)     |      | PRI | 0       |       |
| name        | varchar(25) | YES  |     | NULL    |       |
| address     | varchar(25) | YES  |     | NULL    |       |
| address2    | varchar(25) | YES  |     | NULL    |       |
| city        | varchar(25) | YES  |     | NULL    |       |
| state       | char(2)     | YES  |     | NULL    |       |
| zip         | varchar(10) | YES  |     | NULL    |       |
| client_type | varchar(4)  | YES  |     | NULL    |       |
| status      | char(2)     | YES  |     | NULL    |       |
+-------------+-------------+------+-----+---------+-------+
```

Changing Column Definitions

Use `ALTER TABLE` with `CHANGE` or `MODIFY`.

Change column type (e.g., to ENUM):

The status column name is specified twice even if not changing the name itself when using CHANGE.

```
ALTER TABLE clients
CHANGE status status ENUM('AC','IA');
```

Change column name and keep type:

To change status to active while keeping the ENUM definition:

```
ALTER TABLE clients
CHANGE status active ENUM('AC','IA');
```

When using `CHANGE`, the current column name is followed by the new column name and the complete type definition.

Modify column type or attributes without renaming:

Use MODIFY if you are only changing the data type or attributes, not the name.

```
ALTER TABLE clients
MODIFY address1 VARCHAR(40); -- Assuming 'address1' is an existing column
```

Complex Changes (e.g., ENUM migration with data):

Changing ENUM values in a table with existing data requires careful steps to prevent data loss. This typically involves:

1. Temporarily modifying the ENUM to include both old and new values.
2. Updating existing rows to use the new values.
3. Modifying the ENUM again to remove the old values.

Example of changing `address` to `address1` (40 chars) and preparing `active` ENUM for new values ‘yes’,‘no’ from ‘AC’,‘IA’:

```
ALTER TABLE clients
    CHANGE address address1 VARCHAR(40),
    MODIFY active ENUM('yes','no','AC','IA'); -- Temporarily include all
```

Then, update the data:

```
UPDATE clients
SET active = 'yes'
WHERE active = 'AC';

UPDATE clients
SET active = 'no'
WHERE active = 'IA';
```

Finally, restrict the ENUM to new values:

```
ALTER TABLE clients
MODIFY active ENUM('yes','no');
```

Dropping Columns

To remove a column and its data (this action is permanent and irreversible without a backup):

```
ALTER TABLE clients
DROP COLUMN client_type;
```

Managing Default Values

Set a default value for a column:

If most clients are in ‘LA’, set it as the default for the state column:

```
ALTER TABLE clients
ALTER state SET DEFAULT 'LA';
```

Remove a default value from a column:

This reverts the default to its standard (e.g., NULL if nullable, or determined by data type).

```
ALTER TABLE clients
ALTER state DROP DEFAULT;
```

This `DROP DEFAULT` does not delete existing data in the column.

Managing Indexes

Indexes are separate objects from columns. Modifying an indexed column often requires managing its index.

View existing indexes on a table with `SHOW INDEX`:

The \G displays results in a vertical format, which can be easier to read for wide output.

```
SHOW INDEX FROM clients\G
```

Example output:

```
*************************** 1. row ***************************
           Table: clients
      Non_unique: 0
        Key_name: PRIMARY
    Seq_in_index: 1
     Column_name: cust_id
       Collation: A
     Cardinality: 0
        Sub_part: NULL
          Packed: NULL
         Comment:
```

Changing an indexed column (e.g., Primary Key):

Attempting to CHANGE a column that is part of a PRIMARY KEY without addressing the key might result in an error like “Multiple primary key defined”. The index must be dropped first, then the column changed, and the key re-added.

```
ALTER TABLE clients
    DROP PRIMARY KEY,
    CHANGE cust_id client_id INT PRIMARY KEY;
```

The order is important: `DROP PRIMARY KEY` first.

Changing a column with another index type (e.g., UNIQUE):

If cust_id had a UNIQUE index named cust_id_unique_idx (Key_name from SHOW INDEX):

```
ALTER TABLE clients
    DROP INDEX cust_id_unique_idx, -- Use the actual Key_name
    CHANGE cust_id client_id INT UNIQUE;
```

If the `Key_name` is the same as the `Column_name` (e.g. for a single column `UNIQUE` key defined on `cust_id` where `cust_id` is also its `Key_name`):

```
ALTER TABLE clients
    DROP INDEX cust_id, -- If cust_id is the Key_name
    CHANGE cust_id client_id INT UNIQUE;
```

Changing index type and handling duplicates (e.g., INDEX to UNIQUE):

If changing from an index type that allows duplicates (like a plain INDEX) to one that doesn’t (UNIQUE), and duplicate data exists, the operation will fail. To force the change and remove duplicates (use with extreme caution):

```
ALTER IGNORE TABLE clients
    DROP INDEX cust_id_idx, -- Assuming cust_id_idx is the name of the old INDEX
    CHANGE cust_id client_id INT UNIQUE;
```

The `IGNORE` keyword causes rows with duplicate key values (for the new `UNIQUE` key) to be deleted. Only the first encountered row is kept.

Renaming and Shifting Tables

Rename a table:

To change the name of clients to client_addresses:

```
RENAME TABLE clients TO client_addresses;
```

Move a table to another database (can be combined with renaming):

To move client_addresses to a database named db2:

```
RENAME TABLE client_addresses TO db2.client_addresses;
```

Re-sort data within a table (MyRocks/Aria, not typically InnoDB):

For some storage engines (excluding InnoDB where tables are ordered by the primary key), you can physically reorder rows. This does not usually apply to InnoDB unless the ORDER BY columns form the primary key.

```
ALTER TABLE client_addresses
ORDER BY city, name;
```

After this, `SELECT * FROM client_addresses` (without an `ORDER BY` clause) might return rows in this new physical order, until further data modifications occur.

Key Considerations

- **Backup First:** Always back up tables before making structural alterations, especially on production systems.
- **Data Integrity:** Be mindful of how changes (e.g., type changes, ENUM modifications, dropping columns) can affect existing data. Test changes in a development environment.
- **Irreversible Actions:** Operations like `DROP COLUMN` or `DROP TABLE` are generally irreversible without restoring from a backup. There's typically no confirmation prompt.
- **Indexes:** Understand that indexes are distinct from columns. Modifying indexed columns often requires separate steps to manage the associated indexes.
- **Performance:** `ALTER TABLE` operations on large tables can be time-consuming and resource-intensive, potentially locking the table and impacting application performance. Plan these operations during maintenance windows if possible.

This page is licensed: CC BY-SA / Gnu FDL

Connecting to MariaDB Guide

This guide details the parameters for connecting to a MariaDB server using client programs like `mariadb`. Learn about default connection behaviors and how to use various command-line options to customize your connection, including secure TLS configurations.

While the examples focus on the `mariadb` command-line client, the concepts apply to other clients like graphical interfaces or backup utilities (e.g., `mariadb-dump`). If you are completely new to MariaDB, refer to A MariaDB Primer first.

Default Connection Behavior

When a connection parameter is not explicitly provided, a default value is used. To connect using only default values with the `mariadb` client:

```
mariadb
```

In this scenario, the following defaults typically apply:

- **Host name:** `localhost`
- **User name:** Your Unix login name (on Unix-like systems) or `ODBC` (on Windows).
- **Password:** No password is sent.
- **Database:** The client connects to the server but not to a specific database by default.
- **Socket:** The default socket file is used for connection.

Overriding Defaults

You can override these defaults by specifying parameters. For example:

```
mariadb -h 166.78.144.191 -u username -ppassword database_name
```

In this example:

- `-h 166.78.144.191`: Specifies the host IP address instead of `localhost`.
- `-u username`: Specifies `username` as the MariaDB user.
- `-ppassword`: Specifies `password` as the password.

    - **Note:** For passwords, there must be no space between `-p` and the password value.
    - **Security Warning:** Providing a password directly on the command line is insecure as it can be visible to other users on the system. It's more secure to use `-p` without the password value, which will prompt you to enter it.

- `database_name`: This is the name of the database to connect to, provided as the first argument after all options.
- The connection will use the default TCP/IP port (usually 3306).

Connection Parameters

The following are common connection parameters:

host

- `--host=name`
- `-h name`

Connects to the MariaDB server on the given host.

Default: localhost.

MariaDB typically does not permit remote logins by default; see Configuring MariaDB for Remote Client Access.

password

- `--password[=passwd]`
- `-p[passwd]`

Specifies the password for the MariaDB account.

- **Security Best Practice:** For improved security, use the `-p` or `--password` option without providing the password value directly on the command line. You will be prompted to enter it, preventing it from being visible in command history or process lists.

pipe

- `--pipe`
- `-W`

(Windows only) Connects to the server using a named pipe, if the server was started with the `--enable-named-pipe` option.

port

- `--port=num`
- `-P num`

Specifies the TCP/IP port number for the connection.

Default: 3306.

protocol

- `--protocol=name`

Specifies the connection protocol. Possible values (case-insensitive): `TCP`, `SOCKET`, `PIPE`, `MEMORY`. The default protocol is typically the most efficient for the operating system (e.g., `SOCKET` on Unix).

- **TCP:** TCP/IP connection (local or remote). Available on all OS.

- **SOCKET:** Unix socket file connection (local server on Unix systems only). If `--socket` is not specified, the default is `/tmp/mysql.sock`.
- **PIPE:** Named-pipe connection (local or remote). Windows only.
- **MEMORY:** Shared-memory connection (local server on Windows systems only).

shared-memory-base-name

- `--shared-memory-base-name=name`

(Windows only) Specifies the shared-memory name for connecting to a local server started with the –shared-memory option. The value is case-sensitive.

Default: MARIADB.

socket

- `--socket=name`
- `-S name`

For connections to `localhost`:

- On Unix: Specifies the Unix socket file to use. *Default:* `/tmp/mysql.sock`.
- On Windows: Specifies the name (case-insensitive) of the named pipe if the server was started with `--enable-named-pipe`. *Default:* `MARIADB`.

user

- `--user=name`
- `-u name`

Specifies the MariaDB user name for the connection.

Default: Your Unix login name (on Unix-like systems) or ODBC (on Windows).

See the GRANT command for information on creating MariaDB user accounts.

TLS Options

These options control the use of TLS (Transport Layer Security) for secure connections. For comprehensive details, see Secure Connections Overview and TLS System Variables.

- **`--ssl`**: Enable TLS for the connection. Automatically enabled if other `--ssl-*` flags are used. Disable with `--skip-ssl`.
- **`--ssl-ca=name`**: CA (Certificate Authority) file in PEM format. (Implies `--ssl`).
- **`--ssl-capath=name`**: Directory containing CA certificates in PEM format. (Implies `--ssl`).
- **`--ssl-cert=name`**: Client X.509 certificate in PEM format. (Implies `--ssl`).
- **`--ssl-cipher=name`**: Specific TLS cipher(s) to use for the connection. (Implies `--ssl`).
- **`--ssl-key=name`**: Client X.509 private key in PEM format. (Implies `--ssl`).
- **`--ssl-crl=name`**: Certificate Revocation List (CRL) file in PEM format. (Implies `--ssl`).
- **`--ssl-crlpath=name`**: Directory containing CRL files. (Implies `--ssl`).
- **`--ssl-verify-server-cert`**: Verifies the server's certificate "Common Name" against the hostname used for connecting. Disabled by default.

Option Files

Connection parameters and other options can also be set in option files (configuration files), which most MariaDB clients read upon startup. To see which option files a client reads and the option groups it recognizes, typically run the client with the `--help` option.

Troubleshooting Connection Issues Guide

The guide helps diagnose and resolve common issues encountered when connecting to a MariaDB server. Identify causes for errors like 'Can't connect to local server' or access denied messages, and learn steps to effectively troubleshoot these connection problems.

If you are completely new to MariaDB and relational databases, you may want to start with A MariaDB Primer. Also, ensure you understand the connection parameters discussed in the Connection Parameters Guide.

Server Not Running or Incorrect Location

Symptoms

You receive errors like client error[1] 2002 or client error 2003:

```
ERROR 2002 (HY000): Can't connect to local MySQL server through
  socket '/var/run/mysqld/mysqld.sock' (2 "No such file or directory")
```

```
mariadb -u someuser -p --port=3307 --protocol=tcp
ERROR 2003 (HY000): Can't connect to MySQL server on 'localhost'
  (111 "Connection refused")
```

Causes & Solutions

Server Not Running

The MariaDB server process may not be running. Verify with `mariadb-admin`:

```
$ mariadb-admin status
mariadb-admin: connect to server at 'localhost' failed
error: 'Can't connect to local server through socket '/tmp/mysql.sock' (2)'
Check that mariadbd is running and that the socket: '/tmp/mysql.sock' exists!
```

If the server isn't running, start it using the method applicable to your environment.

Incorrect Parameters

The server is running, but not on the specified host, port, socket, pipe, or protocol. Verify your connection parameters.

- **Socket File Mismatch (Unix):** The socket file path might be non-standard or inconsistent between server and client configurations.
  - Check your configuration file. Ensure the `socket` option has the identical value for both server and client.
  - To find the running Unix socket file, try this command:

    ```
    $ netstat -ln | grep mysqld
    ```

    Example output:

    ```
    unix  2      [ ACC ]     STREAM     LISTENING     33209505 /var/run/mysqld/mysqld.sock
    ```
- See also: Troubleshooting Installation Issues.

Unable to Connect from a Remote Location

Symptoms

You can connect locally, but not from a remote machine, possibly seeing errors like this:

```
$ mariadb --host=myhost --protocol=tcp --port=3306 test
ERROR 2002 (HY000): Can't connect to MySQL server on 'myhost' (115)
```

You can use `telnet` (if available) to test basic network connectivity to the port:

```
$ telnet myhost 3306
```

A "Connection refused" message from `telnet` indicates a network or firewall issue, or that MariaDB is not listening for TCP/IP connections or on that specific interface/port.

The `perror` utility can interpret OS[2] error codes:

```
$ perror 115
```

Example output:

```
OS error code 115: Operation now in progress
```

Causes & Solutions

By default, MariaDB often does not accept remote TCP/IP connections, or is bound only to `localhost` (`127.0.0.1`).

Solution: See Configuring MariaDB for Remote Client Access for detailed instructions on how to enable remote connections by adjusting the `bind-address` server variable and ensuring user accounts are configured correctly for remote hosts.

Authentication Problems

Symptoms

Connection is established, but authentication fails (for instance, "Access denied for user…").

Causes & Solutions

- **Unix Socket Authentication:** On Unix-like systems, the `unix_socket` authentication plugin is enabled by default for local connections via the Unix socket file. This plugin uses operating system user credentials.

    - See the `unix_socket` authentication plugin documentation for connection instructions and how to switch to password-based authentication if needed.
    - For an overview of authentication changes in MariaDB 10.4, see Authentication from MariaDB 10.4.
- **Incorrect Username/Host Combination:** Authentication is specific to a `username@host` combination. For example, `'user1'@'localhost'` is distinct from `'user1'@'166.78.144.191'`. Ensure the user account exists for the host from which you are connecting.
    - See GRANT for details on granting permissions.
- **Password Hashing:** When setting or changing passwords using `SET PASSWORD`, ensure the `PASSWORD()` function is used if the server expects hashed passwords.
    - Example: `SET PASSWORD FOR 'bob'@'%.loc.gov' = PASSWORD('newpass');`
    - Rather than: `SET PASSWORD FOR 'bob'@'%.loc.gov' = 'newpass';` (which might store the password as plain text, potentially leading to issues depending on the authentication plugin).

Problems Exporting Query Results or Loading Data

Symptoms

You can run regular queries, but get authentication or permission errors when using `SELECT ... INTO OUTFILE`, `SELECT ... INTO DUMPFILE`, or `LOAD DATA INFILE`.

Causes & Solutions

- These operations require the `FILE` privilege on the server.
- **Solution:** Grant the necessary `FILE` privilege to the user. See the GRANT article.

Access Denied to a Specific Database

Symptoms

You can connect to the MariaDB server, but attempting to issue the `USE` command or query a specific database results in an error:

```
USE test;
ERROR 1044 (42000): Access denied for user 'youruser'@'yourhost' to database 'test'
```

Or, connecting with `mariadb -u user -p db1` works, but `mariadb -u user -p db2` fails for `db2`.

Causes & Solutions

- The user account has not been granted sufficient privileges for that particular database.
- **Solution:** Grant the required privileges (e.g., `SELECT`, `INSERT`, etc.) on the specific database to the user. See GRANT.

Issues Due to Option Files or Environment Variables

Symptoms

Unexpected connection behavior, or parameter usage that you didn't explicitly provide on the command line.

Causes & Solutions

- Option files (for instance, `my.cnf`, `.my.ini`) or environment variables (for instance, `MYSQL_HOST`) might be supplying incorrect parameters, or overriding connection parameters.
- **Troubleshooting:**

- Check the values in any option files read by your client. See Configuring MariaDB with Option Files and the documentation for the specific client you are using (listed under Clients and Utilities).
- You can often suppress the reading of default option files by using a `--no-defaults` option (if supported by the client):

  ```
  $ mariadb --no-defaults ...
  ```

Unable to Connect / Lost Root Password

Symptoms

You cannot connect to a running server because the root (or other administrative) password is lost or unknown.

Causes & Solutions

- **Solution:** You can start the MariaDB server with the `--skip-grant-tables` option. This bypasses the privilege system, granting full access. **Use this with extreme caution and only temporarily.**
  1. Stop the MariaDB server.
  2. Restart the server manually from the command line, adding the `--skip-grant-tables` option.
  3. Connect to the server (no password is required for `root@localhost`).
  4. Change the password for the account you're connecting with (for example, `root`):

     ```
     SET PASSWORD FOR 'root'@'localhost' = PASSWORD('your_new_strong_password');
     ```

  5. Stop the server, and restart it normally (without `--skip-grant-tables`).

> **Note:**
>
> Before doing this, particularly if you cannot connect to a freshly installed MariaDB server, see if the next solution can solve your problem.

Quick Fix: Access Denied for 'root'@'localhost'?

Starting with MariaDB 10.4, the default security model for Linux installations uses the `unix_socket` authentication plugin. This means the MariaDB `root` user is tied to your system's `root` user.

- **The Problem:** If you try to connect using `mariadb -u root -p`, the server may reject you because it is looking for your operating system identity, not a password.
- **The Solution:** Instead of a password, use `sudo`:

  ```
  sudo mariadb
  ```

- **Why this works:** The server recognizes you have `sudo` (administrative) privileges on the machine and automatically logs you into the MariaDB `root` account without requiring a separate database password.

> **Warning:**
>
> Do not use this as a permanent solution.
>
> Rather than that, use it as a one-off, to be able to connect to the MariaDB Server at all. Once logged in, create a proper user, like `'myuser'@'localhost'`, or even `'myadmin'@'localhost'`. Then, grant the necessary privileges to that user. An administrative user, comparable to `root`, should have privileges to access every object in your database, by running this query:
>
> `GRANT ALL ON *.* to 'myadmin'@'localhost' IDENTIFIED BY '(your_password)' WITH GRANT OPTION`
>
> When done, log out, then log in again, using your newly created user. This is now possible without using the `sudo` workaround:
>
> `mariadb --user myadmin --password` (specify *your_password* when prompted)

`localhost` vs. `%` Wildcard Host Issues

Symptoms

You've created a user like `'melisa'@'%'` but cannot log in as melisa when connecting from `localhost`.

```
-- User created with '%' host
CREATE USER 'melisa'@'%' IDENTIFIED BY 'password';

-- Checking users in mysql.user table
SELECT user, host FROM mysql.user WHERE user='melisa' OR user='';
```

Example output showing the problem:

```
+--------+-----------+
| user   | host      |
+--------+-----------+
| melisa | %         |
|        | localhost | -- An anonymous user for localhost
+--------+-----------+
```

Causes & Solutions

- The MariaDB user authentication prioritizes more specific host matches. If an anonymous user (`''@'localhost'`) exists, it can take precedence over `'melisa'@'%'` when connecting from `localhost`.
- **Solutions:**
  1. Create a specific user for localhost:

     ```
     CREATE USER 'melisa'@'localhost' IDENTIFIED BY 'password_for_melisa_localhost';
     GRANT ALL PRIVILEGES ON yourdatabase.* TO 'melisa'@'localhost'; -- Grant necessary privileges
     ```

  2. Remove the anonymous user for localhost (use with caution):

     ```
     DROP USER ''@'localhost';
     ```

     Ensure this doesn't break other intended anonymous access, if any.

MariaDB Authentication Tutorial

https://www.youtube.com/watch?v=aWFG4uLbimM

MariaDB authentication from MariaDB 10.4

In this video tutorial, the MariaDB team explains the fundamental changes to the security model introduced in version 10.4, specifically regarding how the `root` user and local connections are handled.

Core Topics Covered:

- The “No Password” Default: Explains why, in MariaDB 10.4 and later, the `root` user does not have a password by default on many Linux distributions.
- Unix Socket Authentication: A walkthrough of the `unix_socket` plugin. This plugin allows the OS-level `root` user to log in to the MariaDB `root` account without a password, as security is verified by the operating system identity.
- The `mysql.global_priv` table: Introduction of the new table that replaces the old `mysql.user` table for storing privileges, and how this change simplifies managing multiple authentication methods for a single user.
- Switching Authentication Methods: Practical steps on how to move from socket-based authentication back to traditional password-based authentication (using the `mysql_native_password` plugin) if your environment requires it.

Key Takeaway for Troubleshooting:

If you are receiving an Access Denied error while trying to log in as `root` despite using a password you believe is correct, the video demonstrates that your server is likely expecting Unix Socket authentication. In this case, you should use `sudo mariadb` rather than `mariadb -u root -p`.

Doing Time Guide

This guide covers effective ways to work with date and time information in MariaDB. Learn about temporal data types, essential functions for recording current date/time, extracting specific parts, and formatting your date/time values for display or analysis.

Temporal Data Types

While dates and times can be stored as character strings, using specific temporal data types allows you to leverage MariaDB’s built-in functions for manipulation and formatting.

- **`DATE`**: For dates only. Format: `YYYY-MM-DD`.
- **`TIME`**: For time only. Format: `HHH:MM:SS` (hours can range beyond 24).
- **`DATETIME`**: For combined date and time. Format: `YYYY-MM-DD HH:MM:SS`.
- **`TIMESTAMP`**: Similar to `DATETIME`, but with a more limited range and automatic update capabilities (not covered here). Range typically from `1970-01-01 00:00:01` UTC to `2038-01-19 03:14:07` UTC. From MariaDB 11.5 (64-bit), this range extends to `2106-02-07`.
- **`YEAR`**: For years only. Format: `YY` or `YYYY`.

Recording Current Date and Time

MariaDB provides several functions to get the current date and time.

Current Date:

Use `CURRENT_DATE` (no parentheses) or `CURDATE()` (with parentheses).

```
INSERT INTO billable_work (doctor_id, patient_id, session_date)
VALUES ('1021', '1256', CURRENT_DATE);
```

To see the ID of the last inserted row (if the primary key is `AUTO_INCREMENT`):

```
SELECT rec_id, doctor_id, patient_id, session_date
FROM billable_work
WHERE rec_id = LAST_INSERT_ID();
```

```
+--------+-----------+------------+--------------+
| rec_id | doctor_id | patient_id | session_date |
+--------+-----------+------------+--------------+
|   2462 | 1021      | 1256       | 2025-05-28   | -- Example date
+--------+-----------+------------+--------------+
```

Current Time:

Use `CURRENT_TIME` or `CURTIME()`.

```
UPDATE billable_work
SET session_time = CURTIME()
WHERE rec_id = '2462';

SELECT patient_id, session_date, session_time
FROM billable_work
WHERE rec_id = '2462';
```

```
+------------+--------------+--------------+
| patient_id | session_date | session_time |
+------------+--------------+--------------+
| 1256       | 2025-05-28   | 13:03:22     | -- Example time
+------------+--------------+--------------+
```

Current Date and Time (Timestamp):

Use `CURRENT_TIMESTAMP`, `NOW()`, or `SYSDATE()`. These functions return the current date and time in `YYYY-MM-DD HH:MM:SS` format, suitable for `DATETIME` or `TIMESTAMP` columns.

Extracting Date and Time Parts

Extracting from `DATE` types:

- `YEAR(date_column)`: Extracts the year.
- `MONTH(date_column)`: Extracts the month number (1-12).
- `DAYOFMONTH(date_column)`: Extracts the day of the month (1-31). Also `DAY()`.

```
SELECT
    MONTH(session_date) AS Month,
    DAYOFMONTH(session_date) AS Day,
    YEAR(session_date) AS Year
FROM billable_work
WHERE rec_id = '2462';
```

```
+-------+------+------+
| Month | Day  | Year |
+-------+------+------+
|     5 |   28 | 2025 | -- Example output
+-------+------+------+
```

(The `AS` keyword is used to provide an alias for the output column name.)

Day of the Week:

- `DAYOFWEEK(date_column)`: Returns the weekday index (1=Sunday, 2=Monday, …, 7=Saturday).
- `WEEKDAY(date_column)`: Returns the weekday index (0=Monday, 1=Tuesday, …, 6=Sunday).

Example using `IF()` to determine a billing rate based on the day of the week (Saturday = day 7 for `DAYOFWEEK`):

```
SELECT
    patient_id AS 'Patient ID',
    session_date AS 'Date of Session',
    IF(DAYOFWEEK(session_date) = 7, 1.5, 1.0) AS 'Billing Rate'
FROM billable_work
WHERE rec_id = '2462';
```

The `IF(condition, value_if_true, value_if_false)` function allows conditional logic.

Other Date Part Functions:

- `DAYOFYEAR(date_column)`: Returns the day of the year (1-366).
- `QUARTER(date_column)`: Returns the quarter of the year (1-4).

Example: Selecting sessions in a specific quarter (e.g., Q2):

```
SELECT patient_id, session_date
FROM billable_work
WHERE QUARTER(session_date) = 2;
```

User variables can be used for dynamic queries:

```
SET @target_quarter := 2;
SELECT patient_id, COUNT(*) AS num_sessions
FROM billable_work
WHERE QUARTER(session_date) = @target_quarter AND doctor_id = '1021'
GROUP BY patient_id;
```

Extracting from `TIME` types:

- `HOUR(time_column)`: Extracts the hour.
- `MINUTE(time_column)`: Extracts the minute.
- `SECOND(time_column)`: Extracts the second.

```
SELECT
    HOUR(session_time) AS Hour,
    MINUTE(session_time) AS Minute,
    SECOND(session_time) AS Second
FROM billable_work
WHERE rec_id = '2462';
```

```
+------+--------+--------+
| Hour | Minute | Second |
+------+--------+--------+
|   13 |     03 |     22 | -- Example output
+------+--------+--------+
```

Using `EXTRACT()` for `DATETIME` or `TIMESTAMP` types:

The `EXTRACT(unit FROM datetime_column)` function extracts a specified `unit` from a date/time value.
Common units: `YEAR`, `MONTH`, `DAY`, `HOUR`, `MINUTE`, `SECOND`.
Combined units: `YEAR_MONTH`, `DAY_HOUR`, `HOUR_MINUTE`, etc.

```
SELECT
    patient_name AS Patient,
    EXTRACT(HOUR FROM appointment) AS Hour,
    EXTRACT(MINUTE FROM appointment) AS Minute
FROM billable_work
JOIN patients ON billable_work.patient_id = patients.patient_id
WHERE doctor_id = '1021'
  AND EXTRACT(MONTH FROM appointment) = 5
  AND EXTRACT(DAY FROM appointment) = 28;
```

(For details on joining tables, refer to relevant SQL documentation or a guide like "Essential Queries Guide".)

Using a combined unit:

```
SELECT
    patient_name AS Patient,
    EXTRACT(HOUR_MINUTE FROM appointment) AS AppointmentHM
FROM billable_work
JOIN patients ON billable_work.patient_id = patients.patient_id
WHERE doctor_id = '1021';
```

Output for `HOUR_MINUTE` might be like `1303` (for 13:03).

Formatting Dates and Times for Display

Wordier Date Formats:

- `MONTHNAME(date_column)`: Returns the full name of the month (e.g., 'May').
- `DAYNAME(date_column)`: Returns the full name of the day (e.g., 'Wednesday').

Example using `CONCAT()` to combine parts:

```
SELECT
    patient_name AS Patient,
    CONCAT(
        DAYNAME(appointment), ' - ',
        MONTHNAME(appointment), ' ',
        DAYOFMONTH(appointment), ', ',
        YEAR(appointment)
    ) AS Appointment
FROM billable_work
JOIN patients ON billable_work.patient_id = patients.patient_id
WHERE doctor_id = '1021' AND DATE(appointment) = '2025-05-28'
LIMIT 1;
```

```
+------------------+------------------------------+
| Patient          | Appointment                  |
+------------------+------------------------------+
| Michael Zabalaoui | Wednesday - May 28, 2025     | -- Example
+------------------+------------------------------+
```

Using `DATE_FORMAT(datetime_column, format_string)`:
This function provides extensive formatting options.
Syntax: `DATE_FORMAT(date_value, 'format_options_and_literals')`.

```
SELECT
    patient_name AS Patient,
    DATE_FORMAT(appointment, '%W - %M %e, %Y') AS Appointment
FROM billable_work
JOIN patients ON billable_work.patient_id = patients.patient_id
WHERE doctor_id = '1021' AND DATE_FORMAT(appointment, '%c') = 5 -- Filter by month 5 (May)
LIMIT 1;
```

Common format specifiers:

- `%W`: Full weekday name
- `%M`: Full month name
- `%e`: Day of the month, numeric (1-31)
- `%d`: Day of the month, 2 digits (01-31)
- `%Y`: Year, 4 digits
- `%y`: Year, 2 digits
- `%c`: Month, numeric (1-12)
- `%r`: Time in 12-hour format (hh:mm:ss AM/PM)
- `%T`: Time in 24-hour format (hh:mm:ss)
- `%H`: Hour (00-23)
- `%h` or `%I`: Hour (01-12)
- `%i`: Minutes (00-59)
- `%s` or `%S`: Seconds (00-59)
- `%p`: AM or PM

Example with time:

```
SELECT
    DATE_FORMAT(appointment, '%W - %M %e, %Y at %r') AS Appointment
FROM billable_work
LIMIT 1;
```

```
+-----------------------------------------------+
| Appointment                                   |
+-----------------------------------------------+
| Wednesday - May 28, 2025 at 01:03:22 PM       | -- Example
+-----------------------------------------------+
```

For a complete list of options, see the official DATE_FORMAT() documentation.

Using `TIME_FORMAT(time_column, format_string)`:
Similar to `DATE_FORMAT()`, but uses only time-related format options.

```
SELECT
    patient_name AS Patient,
    TIME_FORMAT(appointment, '%l:%i %p') AS AppointmentTime
FROM billable_work
JOIN patients ON billable_work.patient_id = patients.patient_id
WHERE doctor_id = '1021'
  AND DATE(appointment) = CURDATE();
```

```
+------------------+-----------------+
| Patient          | AppointmentTime |
+------------------+-----------------+
| Michael Zabalaoui |     1:03 PM     | -- Example
+------------------+-----------------+
```

Here, `%l` is hour (1-12) and `%p` adds AM/PM.

Tips for Effective Date/Time Handling

- **Use Appropriate Data Types:** Choose temporal data types (`DATE`, `TIME`, `DATETIME`, `TIMESTAMP`, `YEAR`) over string types for date/time data to leverage built-in functions and ensure data integrity.

- **Leverage Built-in Functions:** MariaDB offers a rich set of functions for date/time manipulation. Use them within your SQL queries to avoid complex logic in your application code.
- **Test Queries:** When dealing with complex date/time logic or formatting, test your SQL statements directly in a MariaDB client (like the `mariadb` command-line tool) to verify results before embedding them in applications.
- **Be Aware of Time Zones:** `TIMESTAMP` values are stored in UTC and converted to/from the session's time zone, while `DATETIME` values are stored "as is" without time zone conversion. Understand how your server and session time zones are configured if working with data across different regions. (Time zone handling is a more advanced topic not fully covered here).

Importing Data Guide

This guide introduces methods and tools for efficiently importing bulk data into MariaDB. Learn to prepare your data, use `LOAD DATA INFILE` and the `mariadb-import` utility, handle common data import challenges, and manage potential constraints.

Preparing Your Data File

The most common approach for bulk importing is to use a delimited text file.

1. **Export Source Data:** Load your data in its original software (e.g., MS Excel, MS Access) and export it as a delimited text file.
   - **Delimiter:** Use a character not commonly found in your data to separate fields. The pipe symbol (`|`) is often a good choice. Tab (`\t`) is also common.
   - **Record Separator:** Use line feeds (`\n`) to separate records.
2. **Align Columns (Recommended for Simplicity):** Ideally, the order and number of columns in your text file should match the target MariaDB table.
   - If the table has extra columns not in your file, they will be filled with their default values (or `NULL`).
   - If your file has extra columns not in the table, you'll need to specify which file columns to load (see "Mapping File Columns to Table Columns" below) or remove them from the text file.
3. **Clean Data:** Remove any header rows or footer information from the text file unless you plan to skip them during import (see `IGNORE N LINES` below).
4. **Upload File:** Transfer the text file to a location accessible by the MariaDB server.
   - Use ASCII mode for FTP transfers to ensure correct line endings.
   - For security, upload data files to non-public directories on the server.

Using `LOAD DATA INFILE`

The `LOAD DATA INFILE` statement is a powerful SQL command for importing data from text files. Ensure the MariaDB user has the `FILE` privilege.

Basic Syntax:

First, connect to MariaDB using the mariadb client and select your target database:

```
USE sales_dept; -- Or your database name
```

Then, load the data:

```
LOAD DATA INFILE '/tmp/prospects.txt'
INTO TABLE prospect_contact
FIELDS TERMINATED BY '|';
```

- Replace `/tmp/prospects.txt` with the actual path to your data file on the server. On Windows, paths use forward slashes (e.g., `'C:/tmp/prospects.txt'`).
- `prospect_contact` is the target table. You can also specify `database_name.table_name`.
- `FIELDS TERMINATED BY '|'` specifies the field delimiter. For tab-delimited, use `'\t'`.
- The default record delimiter is the line feed (`\n`).

Specifying Line Terminators and Enclosing Characters:

If your file has custom line endings or fields enclosed by characters (e.g., quotes):

```
LOAD DATA INFILE '/tmp/prospects.txt'
INTO TABLE prospect_contact
FIELDS TERMINATED BY '|' ENCLOSED BY '"'
LINES STARTING BY '"' TERMINATED BY '"\r\n';
```

- `ENCLOSED BY '"'`: Specifies that fields are enclosed in double quotes.
- `LINES STARTING BY '"'`: Indicates each line starts with a double quote.
- `TERMINATED BY '"\r\n'`: Indicates each line ends with a double quote followed by a Windows-style carriage return and line feed.
- To specify a single quote as an enclosing character, you can escape it or put it within double quotes: `ENCLOSED BY '\''` or `ENCLOSED BY "'"`.

Handling Duplicate Rows

When importing data, you might encounter records with primary key values that already exist in the target table.

- **Default Behavior:** MariaDB attempts to import all rows. If duplicates are found and the table has a primary or unique key that would be violated, an error occurs, and subsequent rows may not be imported.
- **`REPLACE`:** If you want new data from the file to overwrite existing rows with the same primary key:SQL

  ```
  LOAD DATA INFILE '/tmp/prospects.txt'
  REPLACE INTO TABLE prospect_contact
  FIELDS TERMINATED BY '|';
  ```

- **`IGNORE`:** If you want to keep existing rows and skip importing duplicate records from the file:SQL

  ```
  LOAD DATA INFILE '/tmp/prospects.txt'
  IGNORE INTO TABLE prospect_contact
  FIELDS TERMINATED BY '|';
  ```

Importing into Live Tables

If the target table is actively being used, importing data can lock it, preventing access.

- **`LOW_PRIORITY`:** To allow other users to read from the table while the load operation is pending, use `LOW_PRIORITY`. The load will wait until no other clients are reading the table.SQL

  ```
  LOAD DATA LOW_PRIORITY INFILE '/tmp/prospects.txt'
  INTO TABLE prospect_contact
  FIELDS TERMINATED BY '|';
  ```

Without `LOW_PRIORITY` or `CONCURRENT`, the table is typically locked for the duration of the import.

Advanced `LOAD DATA INFILE` Options

Binary Line Endings:

If your file has Windows CRLF line endings and was uploaded in binary mode, you can specify the hexadecimal value:

```
LOAD DATA INFILE '/tmp/prospects.txt'
INTO TABLE prospect_contact
FIELDS TERMINATED BY '|'
LINES TERMINATED BY 0x0d0a; -- 0x0d is carriage return, 0x0a is line feed
```

Note: No quotes around the hexadecimal value.

Skipping Header Lines:

To ignore a certain number of lines at the beginning of the file (e.g., a header row):

SQL

```
LOAD DATA INFILE '/tmp/prospects.txt'
INTO TABLE prospect_contact
FIELDS TERMINATED BY '|'
IGNORE 1 LINES; -- Skips the first line
```

Handling Escaped Characters:

If fields are enclosed by quotes and contain embedded quotes that are escaped by a special character (e.g., # instead of the default backslash \):

```
LOAD DATA INFILE '/tmp/prospects.txt'
INTO TABLE prospect_contact
FIELDS TERMINATED BY '|'
    ENCLOSED BY '"'
    ESCAPED BY '#'
IGNORE 1 LINES;
```

Mapping File Columns to Table Columns:

If the order or number of columns in your text file differs from the target table, you can specify the column mapping at the end of the LOAD DATA INFILE statement.

Assume prospect_contact table has: (row_id INT AUTO_INCREMENT, name_first VARCHAR, name_last VARCHAR, telephone VARCHAR).

And prospects.txt has columns in order: Last Name, First Name, Telephone.

```
LOAD DATA INFILE '/tmp/prospects.txt'
INTO TABLE prospect_contact
FIELDS TERMINATED BY '|' -- Or your actual delimiter, e.g., 0x09 for tab
ENCLOSED BY '"'
ESCAPED BY '#'
IGNORE 1 LINES
(name_last, name_first, telephone);
```

- MariaDB will map data from the file's first column to `name_last`, second to `name_first`, and third to `telephone`.
- The `row_id` column in the table, not being specified in the list, will be filled by its default mechanism (e.g., `AUTO_INCREMENT` or `DEFAULT` value, or `NULL`).

Using the `mariadb-import` Utility

The `mariadb-import` utility (known as `mysqlimport` before MariaDB 10.5) is a command-line program that acts as a wrapper for `LOAD DATA INFILE`. It's useful for scripting imports.

Syntax:

```
mariadb-import --user='your_username' --password='your_password' \
    --fields-terminated-by='|' --lines-terminated-by='\r\n' \
    --replace --low-priority --fields-enclosed-by='"' \
    --fields-escaped-by='#' --ignore-lines='1' --verbose \
    --columns='name_last,name_first,telephone' \
    sales_dept '/tmp/prospect_contact.txt'
```

- This command is run from the system shell, not within the `mariadb` client.
- Lines are continued with `\` for readability here; it can be a single line.
- `--password`: If the password value is omitted, you'll be prompted.
- The database name (`sales_dept`) is specified before the file path.
- **File Naming:** `mariadb-import` expects the text file's name (without extension) to match the target table name (e.g., `prospect_contact.txt` for table `prospect_contact`). If your file is `prospects.txt` and table is `prospect_contact`, you might need to rename the file or import into a temporary table named `prospects` first.
- `--verbose`: Shows progress information.
- You can list multiple text files to import into correspondingly named tables.

Dealing with Web Hosting Restraints

Some web hosts disable `LOAD DATA INFILE` or `mariadb-import` for security reasons. A workaround involves using `mariadb-dump`:

1. **Prepare Data Locally:** Prepare your delimited text file (e.g., `prospects.txt`).
2. **Local Import:** If you have a local MariaDB server, import the text file into a local table (e.g., `local_db.prospect_contact`) using `LOAD DATA INFILE` as described above.
3. **Local Export with `mariadb-dump`:** Export the data from your local table into an SQL file containing `INSERT` statements.

   ```
   mariadb-dump --user='local_user' --password='local_pass' --no-create-info local_db prospect_contact > /tmp/prospects.sql
   ```

   - `--no-create-info` (or `-t`): Prevents the `CREATE TABLE` statement from being included, outputting only `INSERT` statements. This is useful if the table already exists on the remote server.
4. **Upload SQL File:** Upload the generated `.sql` file (e.g., `prospects.sql`) to your web server (in ASCII mode).
5. **Remote Import of SQL File:** Log into your remote server's shell and import the SQL file using the `mariadb` client:

   ```
   mariadb --user='remote_user' --password='remote_pass' remote_sales_dept < /tmp/prospects.sql
   ```

Handling Duplicates with mariadb-dump Output:

mariadb-dump does not have a REPLACE flag like LOAD DATA INFILE. If the target table might contain duplicates:

- Open the `.sql` file generated by `mariadb-dump` in a text editor.
- Perform a search and replace operation to change all occurrences of `INSERT INTO` to `REPLACE INTO`. The syntax for `INSERT` and `REPLACE` (for the data values part) is similar enough that this often works. Test thoroughly.

Key Considerations

- **Flexibility:** MariaDB provides powerful and flexible options for data importing. Understanding the details of `LOAD DATA INFILE` and `mariadb-import` can save significant effort.
- **Data Validation:** While these tools are efficient for bulk loading, they may not perform extensive data validation beyond basic type compatibility. Cleanse and validate your data as much as possible before importing.
- **Character Sets:** Ensure your data file's character set is compatible with the target table's character set to avoid data corruption. You can specify character sets in `LOAD DATA INFILE`.
- **Other Tools/Methods:** For very complex transformations or ETL (Extract, Transform, Load) processes, dedicated ETL tools or scripting languages (e.g., Python, Perl with database modules) might be more suitable, though they are beyond the scope of this guide.

Essentials of an Index Guide

An index on `Last_Name` organizes the records by surname, enhancing search efficiency without altering the original table order. Indices can be created for any column, such as ID or first name, to enable quick lookups based on different criteria.

Imagine you've created a table with the following rows:

```
+----+------------+-----------+-------------------------+---------------------------+--------------+
| ID | First_Name | Last_Name | Position                | Home_Address              | Home_Phone   |
+----+------------+-----------+-------------------------+---------------------------+--------------+
|  1 | Mustapha   | Mond      | Chief Executive Officer | 692 Promiscuous Plaza     | 326-555-3492 |
|  2 | Henry      | Foster    | Store Manager           | 314 Savage Circle         | 326-555-3847 |
|  3 | Bernard    | Marx      | Cashier                 | 1240 Ambient Avenue       | 326-555-8456 |
|  4 | Lenina     | Crowne    | Cashier                 | 281 Bumblepuppy Boulevard | 328-555-2349 |
|  5 | Fanny      | Crowne    | Restocker               | 1023 Bokanovsky Lane      | 326-555-6329 |
|  6 | Helmholtz  | Watson    | Janitor                 | 944 Soma Court            | 329-555-2478 |
+----+------------+-----------+-------------------------+---------------------------+--------------+
```

Now, imagine you've been asked to return the home phone of Fanny Crowne. Without indexes, the only way to do it is to go through every row until you find the matching first name and surname. Now imagine there are millions of records and you can see that, even for a speedy database server, this is highly inefficient.

The answer is to sort the records. If they were stored in alphabetical order by surname, even a human could quickly find a record amongst a large number. But we can't sort the entire record by surname. What if we want to also look a record by ID, or by first name? The answer is to create separate indexes for each column we wish to sort by. An index simply contains the sorted data (such as surname), and a link to the original record.

For example, an index on Last_Name:

```
+-----------+----+
| Last_Name | ID |
+-----------+----+
| Crowne    |  4 |
| Crowne    |  5 |
| Foster    |  2 |
| Marx      |  3 |
| Mond      |  1 |
| Watson    |  6 |
+-----------+----+
```

and an index on Position

```
+-------------------------+----+
| Position                | ID |
+-------------------------+----+
| Cashier                 |  3 |
| Cashier                 |  4 |
| Chief Executive Officer |  1 |
| Janitor                 |  6 |
| Restocker               |  5 |
| Store Manager           |  2 |
+-------------------------+----+
```

would allow you to quickly find the phone numbers of all the cashiers, or the phone number of the employee with the surname Marx, very quickly.

Where possible, you should create an index for each column that you search for records by, to avoid having the server read every row of a table.

See CREATE INDEX and Getting Started with Indexes for more information.

Getting Started with Indexes Guide

This guide explains the different types of indexes in MariaDB, their characteristics, and how they are used. Learn to create and manage Primary Keys, Unique Indexes, and Plain Indexes, along with key considerations for choosing and maintaining effective indexes for optimal query performance.

In MariaDB, the terms `KEY` and `INDEX` are generally used interchangeably in SQL statements. For a gentler conceptual overview, see The Essentials of an Index.

Index Types Overview

There are four main kinds of indexes:

- **Primary Keys:** Unique and not NULL.
- **Unique Indexes:** Must be unique but can contain NULL values.
- **Plain Indexes (or Regular Indexes):** Not necessarily unique.
- **Full-Text Indexes:** Used for full-text searching capabilities.

Primary Key

A primary key uniquely identifies each record in a table. Its values must be unique, and it cannot contain `NULL` values. Each table can have only one primary key.

InnoDB Considerations:

- In InnoDB tables, the primary key is included as a suffix in all other indexes. Therefore, keeping the primary key compact (e.g., using an appropriate integer type) is important for performance and storage efficiency.
- If a table has no explicitly defined primary key and no `UNIQUE` indexes, InnoDB automatically creates an invisible 6-byte clustered index.

Using `AUTO_INCREMENT`: The `AUTO_INCREMENT` attribute is commonly used with numeric primary keys to automatically generate a unique ID for each new row.

```
CREATE TABLE `Employees` (
  `ID` TINYINT(3) UNSIGNED NOT NULL AUTO_INCREMENT,
  `First_Name` VARCHAR(25) NOT NULL,
  `Last_Name` VARCHAR(25) NOT NULL,
  `Position` VARCHAR(25) NOT NULL,
  PRIMARY KEY (`ID`)
);
```

Note: The column defined as a primary key (or part of it) must be explicitly declared as `NOT NULL`.

Adding a Primary Key to an Existing Table: Use `ALTER TABLE`. You cannot create a primary key with `CREATE INDEX`.

```
ALTER TABLE Employees ADD PRIMARY KEY(ID);
```

Finding Tables Without Primary Keys: This query uses the `information_schema` database to find tables lacking primary keys:

```
SELECT t.TABLE_SCHEMA, t.TABLE_NAME
FROM information_schema.TABLES AS t
LEFT JOIN information_schema.KEY_COLUMN_USAGE AS c
ON t.TABLE_SCHEMA = c.CONSTRAINT_SCHEMA
   AND t.TABLE_NAME = c.TABLE_NAME
   AND c.CONSTRAINT_NAME = 'PRIMARY'
WHERE t.TABLE_SCHEMA NOT IN ('information_schema', 'performance_schema', 'mysql', 'sys')
  AND c.CONSTRAINT_NAME IS NULL;
```

Unique Index

A unique index ensures that all values in the indexed column (or combination of columns) are unique. However, unlike a primary key, columns in a unique index can store `NULL` values.

Each key value uniquely identifies a row, but not every row needs to be represented if `NULL`s are allowed.

Behavior (MariaDB 10.5+):

- If the index type is not specified, `UNIQUE` typically creates a BTREE index, usable by the optimizer.
- If a key exceeds the maximum length for the storage engine and the engine supports long unique indexes, a HASH key might be created to enforce uniqueness.

Creating Unique Indexes: During table creation:

```
CREATE TABLE `Employees` (
  `ID` TINYINT(3) UNSIGNED NOT NULL,
  `Employee_Code` VARCHAR(25) NOT NULL,
  `First_Name` VARCHAR(25) NOT NULL,
  PRIMARY KEY (`ID`),
  UNIQUE KEY `UK_EmpCode` (`Employee_Code`) -- Naming the unique key is good practice
);
```

After table creation using `ALTER TABLE`:

```
ALTER TABLE Employees ADD UNIQUE `UK_HomePhone` (`Home_Phone`);
```

After table creation using `CREATE UNIQUE INDEX`:

```
CREATE UNIQUE INDEX `IX_Position` ON Employees(Position);
```

Multi-Column Unique Indexes: An index can span multiple columns. MariaDB can use the leftmost part(s) of such an index if it cannot use the whole index (except for HASH indexes).

```
CREATE TABLE t1 (a INT NOT NULL, b INT, UNIQUE (a,b));
INSERT INTO t1 VALUES (1,1), (2,2);
INSERT INTO t1 VALUES (2,1); -- Valid: (2,1) is unique, though '2' in 'a' and '1' in 'b' are not
individually unique here.
SELECT * FROM t1;
```

```
+---+------+
| a | b    |
+---+------+
| 1 |    1 |
| 2 |    1 |
| 2 |    2 |
+---+------+
```

`NULL` Values in Unique Indexes: A `UNIQUE` constraint allows multiple `NULL` values because in SQL, `NULL` is never equal to another `NULL`.

```
INSERT INTO t1 VALUES (3,NULL), (3, NULL); -- Both rows are inserted
SELECT * FROM t1;
```

```
+---+------+
| a | b    |
+---+------+
| 1 |    1 |
| 2 |    1 |
| 2 |    2 |
| 3 | NULL |
| 3 | NULL |
+---+------+
```

Verification:

```
SELECT (3, NULL) = (3, NULL);
```

```
+-----------------------+
| (3, NULL) = (3, NULL) |
+-----------------------+
|                     0 | -- 0 means false
+-----------------------+
```

Conditional Uniqueness with Virtual Columns: You can enforce uniqueness over a subset of rows using unique indexes on virtual columns. This example ensures `user_name` is unique for 'Active' or 'On-Hold' users, but allows duplicate names for 'Deleted' users:

```
CREATE TABLE Table_1 (
  user_name VARCHAR(10),
  status ENUM('Active', 'On-Hold', 'Deleted'),
  del CHAR(0) AS (IF(status IN ('Active', 'On-Hold'), '', NULL)) PERSISTENT,
  UNIQUE(user_name, del)
);
```

Trailing Pad Characters: If a unique index is on a column where trailing pad characters are stripped or ignored (e.g., `CHAR` vs `VARCHAR` behavior), inserts where values differ only by the number of trailing pad characters can result in duplicate-key errors.

Long Keys and HASH Indexes (MariaDB 10.4+): For engines like InnoDB, `UNIQUE` can be used with various column types and numbers. If a key's length exceeds the engine's maximum, a HASH key may be created.

```
-- Example table definition (simplified for brevity)
CREATE TABLE t_long_keys (
  a INT PRIMARY KEY,
  b BLOB,
  c1 VARCHAR(1000),
  UNIQUE KEY `uk_b` (b),
  UNIQUE KEY `uk_c1` (c1)
) ENGINE=InnoDB;

-- SHOW CREATE TABLE might reveal 'USING HASH' for uk_b or uk_c1 if they exceed length limits
SHOW CREATE TABLE t_long_keys\G
```

Example output snippet showing `USING HASH`:

```
...
  UNIQUE KEY `uk_b` (`b`) USING HASH,
...
```

Plain Indexes (Regular Indexes)

Plain indexes do not enforce uniqueness; they are primarily used to speed up data retrieval.

```
CREATE TABLE t2 (a INT NOT NULL, b INT, INDEX `idx_a_b` (a,b));
INSERT INTO t2 VALUES (1,1), (2,2), (2,2); -- Duplicate (2,2) is allowed
SELECT * FROM t2;
```

```
+---+------+
| a | b    |
+---+------+
| 1 |    1 |
| 2 |    2 |
| 2 |    2 |
+---+------+
```

Full-Text Indexes

Full-text indexes are used for performing full-text searches on text data. For details, see the Full-Text Indexes documentation.

Choosing Indexes

- **Index for Queries:** Add indexes that match the `WHERE` clauses, `JOIN` conditions, and `ORDER BY` clauses of your application's queries.
- **Avoid Over-Indexing:** Extra indexes consume storage and can slow down `INSERT`, `UPDATE`, and `DELETE` operations.
- **Impact of Table Size:** Indexes provide more significant speed-ups on large tables (larger than buffer sizes) than on very small tables.
- **Use `EXPLAIN`:** Analyze your queries with the `EXPLAIN` statement to determine if indexes are being used effectively and identify columns that might benefit from indexing.
- **`LIKE '%word%'`:** Queries using a leading wildcard in a `LIKE` clause (e.g., `LIKE '%word%'`) typically cannot use standard BTREE indexes effectively and may result in full table scans unless a full-text index is used.
- **Delayed Writes:** For tables with many reads and writes, consider storage engine options or server configurations related to delayed writes to potentially improve performance by batching disk I/O. (This is an advanced topic.)
- **Creating Indexes on Existing Tables:** Use `CREATE INDEX index_name ON table_name (column_list);`
- **Large Tables:** For very large tables, it's often faster to load data into the table first and then create indexes, rather than creating indexes on an empty table and then loading data.

Viewing Indexes

- **`SHOW INDEX FROM table_name;`** : Displays information about all indexes on a table.

```
SHOW INDEX FROM Employees;
```

- **`SHOW CREATE TABLE table_name;`** : Shows the `CREATE TABLE` statement, which includes definitions for all indexes.SQL

```
SHOW CREATE TABLE Employees\G
```

When to Remove an Index

Remove an index if:

- It is rarely or never used. Unused indexes still incur overhead during data modification operations.
- **Identifying Unused Indexes:**
  - If user statistics are enabled, query the `information_schema.INDEX_STATISTICS` table.
  - If the slow query log is enabled and the `log_queries_not_using_indexes` server system variable is `ON`, queries performing full table scans will be logged, which can indicate missing or ineffective indexes.

Joining Tables with JOIN Clauses

This guide offers a simple, hands-on introduction to three basic `JOIN` types in MariaDB: `INNER JOIN`, `CROSS JOIN`, and `LEFT JOIN`. Use these examples to understand how different joins combine data from multiple tables based on specified conditions.

Setup: Example Tables and Data

First, create and populate two simple tables, `t1` and `t2`, to use in the `JOIN` examples:

```
CREATE TABLE t1 ( a INT );
CREATE TABLE t2 ( b INT );

INSERT INTO t1 VALUES (1), (2), (3);
INSERT INTO t2 VALUES (2), (4);
```

JOIN Examples and Output

Below are examples of different `JOIN` types using the tables `t1` and `t2`.

INNER JOIN

An `INNER JOIN` produces a result set containing only rows that have a match in both tables for the specified join condition(s).

```
SELECT * FROM t1 INNER JOIN t2 ON t1.a = t2.b;
```

Output:

```
+------+------+
| a    | b    |
+------+------+
|    2 |    2 |
+------+------+
1 row in set (0.00 sec)
```

Explanation: Only the row where `t1.a` (value 2) matches `t2.b` (value 2) is returned.

CROSS JOIN

A `CROSS JOIN` produces a result set in which every row from the first table is joined to every row in the second table. This is also known as a Cartesian product.

```
SELECT * FROM t1 CROSS JOIN t2;
```

Output:

```
+------+------+
| a    | b    |
+------+------+
|    1 |    2 |
|    2 |    2 |
|    3 |    2 |
|    1 |    4 |
|    2 |    4 |
|    3 |    4 |
+------+------+
6 rows in set (0.00 sec)
```

Explanation: Each of the 3 rows in `t1` is combined with each of the 2 rows in `t2`, resulting in 3 * 2 = 6 rows. *Note:* In MariaDB, the `CROSS` keyword can often be omitted if no `ON` clause is present (e.g., `SELECT * FROM t1 JOIN t2;` or `SELECT * FROM t1, t2;` would also produce a Cartesian product).

LEFT JOIN (t1 LEFT JOIN t2)

A `LEFT JOIN` (or `LEFT OUTER JOIN`) produces a result set with all rows from the "left" table (`t1` in this case). If a match is found in the "right" table (`t2`), the corresponding columns from the right table are included. If no match is found, these columns are filled with `NULL`.

```
SELECT * FROM t1 LEFT JOIN t2 ON t1.a = t2.b;
```

Output:

```
+------+------+
| a    | b    |
+------+------+
|    1 | NULL |
|    2 |    2 |
|    3 | NULL |
+------+------+
3 rows in set (0.00 sec)
```

Explanation: All rows from `t1` are present. For `t1.a = 1` and `t1.a = 3`, there are no matching `t2.b` values, so `b` is `NULL`. For `t1.a = 2`, a match is found (`t2.b = 2`), so `b` is `2`.

> Starting with MariaDB 12.3, multiple independent `LEFT JOIN` operations can be reordered by the optimizer for better performance if the reorder_outer_joins flag is enabled in optimizer_switch. It is also recommended to set `optimizer_prune_level=0` to prevent heuristic pruning from eliminating optimal join orders.

RIGHT JOIN (t1 RIGHT JOIN t2)

A `RIGHT JOIN` (or `RIGHT OUTER JOIN`) produces a result set with all rows from the "right" table (`t2` in this case). If a match is found in the "left" table (`t1`), the corresponding columns from the left table are included. If no match is found, these columns are filled with `NULL`.

```
SELECT * FROM t1 RIGHT JOIN t2 ON t1.a = t2.b;
```

Output:

```
+------+------+
| a    | b    |
+------+------+
|    2 |    2 |
| NULL |    4 |
+------+------+
2 rows in set (0.00 sec)
```

LEFT JOIN (t2 LEFT JOIN t1) - Simulating a RIGHT JOIN

This example uses a `LEFT JOIN` but with `t2` as the left table. This effectively demonstrates how a `RIGHT JOIN` would behave if `t1` were the left table and `t2` the right. A `RIGHT JOIN` includes all rows from the "right" table and `NULL`s for non-matching "left" table columns.

```
SELECT * FROM t2 LEFT JOIN t1 ON t1.a = t2.b;
```

Output:

```
+------+------+
| b    | a    |
+------+------+
|    2 |    2 |
|    4 | NULL |
+------+------+
2 rows in set (0.00 sec)
```

Explanation: All rows from `t2` are present. For `t2.b = 2`, a match is found (`t1.a = 2`), so `a` is `2`. For `t2.b = 4`, there is no matching `t1.a` value, so `a` is `NULL`.

Older (Implicit) JOIN Syntax

The first two `SELECT` statements (`INNER JOIN` and `CROSS JOIN`) are sometimes written using an older, implicit join syntax:

- **Implicit INNER JOIN:**

  ```
  SELECT * FROM t1, t2 WHERE t1.a = t2.b;
  ```

  This is equivalent to `SELECT * FROM t1 INNER JOIN t2 ON t1.a = t2.b;`.

- **Implicit CROSS JOIN (Cartesian Product):**

  ```
  SELECT * FROM t1, t2;
  ```

  This is equivalent to `SELECT * FROM t1 CROSS JOIN t2;`.

While this syntax works, the explicit `JOIN` syntax (`INNER JOIN`, `LEFT JOIN`, etc.) with an `ON` clause is generally preferred for clarity and to better distinguish join conditions from filtering conditions (`WHERE` clause).

Understanding JOIN Types Summary

- **`INNER JOIN`**: Returns rows only when there is a match in both tables based on the join condition.
- **`CROSS JOIN`**: Returns the Cartesian product of the two tables (all possible combinations of rows).
- **`LEFT JOIN` (Outer Join)**: Returns all rows from the left table, and the matched rows from the right table. If there is no match, `NULL` is returned for columns from the right table.

- **`RIGHT JOIN` (Outer Join)**: Returns all rows from the right table, and the matched rows from the left table. If there is no match, `NULL` is returned for columns from the left table. (The example `SELECT * FROM t2 LEFT JOIN t1 ...` shows this behavior from `t1`'s perspective).

Joining Multiple Tables

`JOIN` clauses can be concatenated (chained) to retrieve results from three or more tables by progressively joining them.

Advanced Joins

This article is a continuation of the Joining Tables with JOIN Clauses Guide. If you're getting started with `JOIN` statements, review that page first.

The Employee Database

Let us begin by using an example employee database of a fairly small family business, which does not anticipate expanding in the future.

First, we create the table that will hold all of the employees and their contact information:

```
CREATE TABLE `Employees` (
  `ID` TINYINT(3) UNSIGNED NOT NULL AUTO_INCREMENT,
  `First_Name` VARCHAR(25) NOT NULL,
  `Last_Name` VARCHAR(25) NOT NULL,
  `Position` VARCHAR(25) NOT NULL,
  `Home_Address` VARCHAR(50) NOT NULL,
  `Home_Phone` VARCHAR(12) NOT NULL,
  PRIMARY KEY (`ID`)
) ENGINE=MyISAM;
```

Next, we add a few employees to the table:

```
INSERT INTO `Employees` (`First_Name`, `Last_Name`, `Position`, `Home_Address`, `Home_Phone`)
  VALUES
  ('Mustapha', 'Mond', 'Chief Executive Officer', '692 Promiscuous Plaza', '326-555-3492'),
  ('Henry', 'Foster', 'Store Manager', '314 Savage Circle', '326-555-3847'),
  ('Bernard', 'Marx', 'Cashier', '1240 Ambient Avenue', '326-555-8456'),
  ('Lenina', 'Crowne', 'Cashier', '281 Bumblepuppy Boulevard', '328-555-2349'),
  ('Fanny', 'Crowne', 'Restocker', '1023 Bokanovsky Lane', '326-555-6329'),
  ('Helmholtz', 'Watson', 'Janitor', '944 Soma Court', '329-555-2478');
```

Now, we create a second table, containing the hours which each employee clocked in and out during the week:

```
CREATE TABLE `Hours` (
  `ID` TINYINT(3) UNSIGNED NOT NULL,
  `Clock_In` DATETIME NOT NULL,
  `Clock_Out` DATETIME NOT NULL
) ENGINE=MyISAM;
```

Finally, although it is a lot of information, we add a full week of hours for each of the employees into the second table that we created:

```
INSERT INTO `Hours`
  VALUES
  ('1', '2005-08-08 07:00:42', '2005-08-08 17:01:36'),
  ('1', '2005-08-09 07:01:34', '2005-08-09 17:10:11'),
  ('1', '2005-08-10 06:59:56', '2005-08-10 17:09:29'),
  ('1', '2005-08-11 07:00:17', '2005-08-11 17:00:47'),
  ('1', '2005-08-12 07:02:29', '2005-08-12 16:59:12'),
  ('2', '2005-08-08 07:00:25', '2005-08-08 17:03:13'),
  ('2', '2005-08-09 07:00:57', '2005-08-09 17:05:09'),
  ('2', '2005-08-10 06:58:43', '2005-08-10 16:58:24'),
  ('2', '2005-08-11 07:01:58', '2005-08-11 17:00:45'),
  ('2', '2005-08-12 07:02:12', '2005-08-12 16:58:57'),
  ('3', '2005-08-08 07:00:12', '2005-08-08 17:01:32'),
  ('3', '2005-08-09 07:01:10', '2005-08-09 17:00:26'),
  ('3', '2005-08-10 06:59:53', '2005-08-10 17:02:53'),
  ('3', '2005-08-11 07:01:15', '2005-08-11 17:04:23'),
  ('3', '2005-08-12 07:00:51', '2005-08-12 16:57:52'),
  ('4', '2005-08-08 06:54:37', '2005-08-08 17:01:23'),
  ('4', '2005-08-09 06:58:23', '2005-08-09 17:00:54'),
  ('4', '2005-08-10 06:59:14', '2005-08-10 17:00:12'),
  ('4', '2005-08-11 07:00:49', '2005-08-11 17:00:34'),
  ('4', '2005-08-12 07:01:09', '2005-08-12 16:58:29'),
  ('5', '2005-08-08 07:00:04', '2005-08-08 17:01:43'),
  ('5', '2005-08-09 07:02:12', '2005-08-09 17:02:13'),
  ('5', '2005-08-10 06:59:39', '2005-08-10 17:03:37'),
  ('5', '2005-08-11 07:01:26', '2005-08-11 17:00:03'),
  ('5', '2005-08-12 07:02:15', '2005-08-12 16:59:02'),
  ('6', '2005-08-08 07:00:12', '2005-08-08 17:01:02'),
  ('6', '2005-08-09 07:03:44', '2005-08-09 17:00:00'),
  ('6', '2005-08-10 06:54:19', '2005-08-10 17:03:31'),
  ('6', '2005-08-11 07:00:05', '2005-08-11 17:02:57'),
  ('6', '2005-08-12 07:02:07', '2005-08-12 16:58:23');
```

Working with the Employee Database

Now that we have a cleanly structured database to work with, let us begin this tutorial by stepping up one notch from the last tutorial and filtering our information a little.

Filtering by Name

Earlier in the week, an anonymous employee reported that Helmholtz came into work almost four minutes late; to verify this, we will begin our investigation by filtering out employees whose first names are “Helmholtz”:

```
SELECT
  `Employees`.`First_Name`,
  `Employees`.`Last_Name`,
  `Hours`.`Clock_In`,
  `Hours`.`Clock_Out`
FROM `Employees`
INNER JOIN `Hours` ON `Employees`.`ID` = `Hours`.`ID`
WHERE `Employees`.`First_Name` = 'Helmholtz';
```

The result looks like this:

```
+------------+-----------+---------------------+---------------------+
| First_Name | Last_Name | Clock_In            | Clock_Out           |
+------------+-----------+---------------------+---------------------+
| Helmholtz  | Watson    | 2005-08-08 07:00:12 | 2005-08-08 17:01:02 |
| Helmholtz  | Watson    | 2005-08-09 07:03:44 | 2005-08-09 17:00:00 |
| Helmholtz  | Watson    | 2005-08-10 06:54:19 | 2005-08-10 17:03:31 |
| Helmholtz  | Watson    | 2005-08-11 07:00:05 | 2005-08-11 17:02:57 |
| Helmholtz  | Watson    | 2005-08-12 07:02:07 | 2005-08-12 16:58:23 |
+------------+-----------+---------------------+---------------------+
5 rows in set (0.00 sec)
```

This is obviously more information than we care to trudge through, considering we only care about when he arrived past 7:00:59 on any given day within this week; thus, we need to add a couple more conditions to our `WHERE` clause.

Filtering by Name, Date and Time

In the following example, we will filter out all of the times which Helmholtz clocked in that were before 7:01:00 and during the work week that lasted from the 8th to the 12th of August:

```
SELECT
  `Employees`.`First_Name`,
  `Employees`.`Last_Name`,
  `Hours`.`Clock_In`,
  `Hours`.`Clock_Out`
FROM `Employees`
INNER JOIN `Hours` ON `Employees`.`ID` = `Hours`.`ID`
WHERE `Employees`.`First_Name` = 'Helmholtz'
AND DATE_FORMAT(`Hours`.`Clock_In`, '%Y-%m-%d') >= '2005-08-08'
AND DATE_FORMAT(`Hours`.`Clock_In`, '%Y-%m-%d') <= '2005-08-12'
AND DATE_FORMAT(`Hours`.`Clock_In`, '%H:%i:%S') > '07:00:59';
```

The result looks like this:

```
+------------+-----------+---------------------+---------------------+
| First_Name | Last_Name | Clock_In            | Clock_Out           |
+------------+-----------+---------------------+---------------------+
| Helmholtz  | Watson    | 2005-08-09 07:03:44 | 2005-08-09 17:00:00 |
| Helmholtz  | Watson    | 2005-08-12 07:02:07 | 2005-08-12 16:58:23 |
+------------+-----------+---------------------+---------------------+
2 rows in set (0.00 sec)
```

By merely adding a few more conditions, we eliminated all of the irrelevant information; Helmholtz was late to work on the 9th and the 12th of August.

Displaying Total Work Hours per Day

Suppose you would like to—based on the information stored in both of our tables in the employee database—develop a quick list of the total hours each employee has worked for each day recorded; a simple way to estimate the time each employee worked per day is exemplified below:

```
SELECT
  `Employees`.`ID`,
  `Employees`.`First_Name`,
  `Employees`.`Last_Name`,
  `Hours`.`Clock_In`,
  `Hours`.`Clock_Out`,
DATE_FORMAT(`Hours`.`Clock_Out`, '%T')-DATE_FORMAT(`Hours`.`Clock_In`, '%T')
AS 'Total_Hours'
FROM `Employees`
INNER JOIN `Hours` ON `Employees`.`ID` = `Hours`.`ID`;
```

The result (limited to 10 rows) looks like this:

```
+----+------------+-----------+---------------------+---------------------+-------------+
| ID | First_Name | Last_Name | Clock_In            | Clock_Out           | Total_Hours |
+----+------------+-----------+---------------------+---------------------+-------------+
|  1 | Mustapha   | Mond      | 2005-08-08 07:00:42 | 2005-08-08 17:01:36 |          10 |
|  1 | Mustapha   | Mond      | 2005-08-09 07:01:34 | 2005-08-09 17:10:11 |          10 |
|  1 | Mustapha   | Mond      | 2005-08-10 06:59:56 | 2005-08-10 17:09:29 |          11 |
|  1 | Mustapha   | Mond      | 2005-08-11 07:00:17 | 2005-08-11 17:00:47 |          10 |
|  1 | Mustapha   | Mond      | 2005-08-12 07:02:29 | 2005-08-12 16:59:12 |           9 |
|  2 | Henry      | Foster    | 2005-08-08 07:00:25 | 2005-08-08 17:03:13 |          10 |
|  2 | Henry      | Foster    | 2005-08-09 07:00:57 | 2005-08-09 17:05:09 |          10 |
|  2 | Henry      | Foster    | 2005-08-10 06:58:43 | 2005-08-10 16:58:24 |          10 |
|  2 | Henry      | Foster    | 2005-08-11 07:01:58 | 2005-08-11 17:00:45 |          10 |
|  2 | Henry      | Foster    | 2005-08-12 07:02:12 | 2005-08-12 16:58:57 |           9 |
+----+------------+-----------+---------------------+---------------------+-------------+
10 rows in set (0.00 sec)
```

Configuring MariaDB for Remote Client Access Guide

This guide explains how to configure your MariaDB server to accept connections from remote hosts. Learn to adjust crucial network settings like `bind-address`, grant appropriate user privileges for remote connections, and configure essential firewall rules.

Understanding Key Network Directives

Two main configuration directives control MariaDB's network accessibility:

- **`skip-networking`**: If this directive is enabled, MariaDB will not listen for TCP/IP connections at all. All interaction must be through local mechanisms like Unix sockets or named pipes.
- **`bind-address`**: This directive specifies the IP address the server listens on.
  - By default, for security, many MariaDB packages bind to `127.0.0.1` (localhost). This means the server will only accept connections originating from the server machine itself via the loopback interface. Remote connections will fail.
  - If `bind-address` is set to `127.0.0.1`, attempting to connect from another host, or even from the same host using a non-loopback IP address, will result in errors like:

    ```
    ERROR 2002 (HY000): Can't connect to MySQL server on 'myhost' (115)
    ```

    A `telnet myhost 3306` test would likely show "Connection refused."
  - To allow connections from other hosts, you must either comment out the `bind-address` directive (making MariaDB listen on all available network interfaces, i.e., `0.0.0.0` for IPv4), or set it to a specific public IP address of the server.
  - **MariaDB 10.11 and later:** `bind-address` can accept multiple comma-separated IP addresses, allowing the server to listen on specific interfaces while excluding others.

Connecting via `localhost` typically works even if `bind-address` is `127.0.0.1` (using the loopback interface):

```
./client/mariadb --host=localhost --protocol=tcp --port=3306 test
```

Locating the MariaDB Configuration File

To change these network settings, you need to edit MariaDB's configuration file (often named `my.cnf` or `my.ini`).

- See Configuring MariaDB with my.cnf for comprehensive details.
- **Common Locations:**
  - `/etc/my.cnf` (Unix/Linux/BSD)
  - `/etc/mysql/my.cnf` (Common on Debian/Ubuntu)
  - `$MYSQL_HOME/my.cnf` (Unix/Linux/BSD, where `$MYSQL_HOME` is MariaDB's base directory)
  - `SYSCONFDIR/my.cnf` (Compile-time specified system configuration directory)
  - `DATADIR\my.ini` (Windows, in the data directory)
  - `~/.my.cnf` (User-specific configuration file)
- **Identifying Loaded Files:** To see which configuration files your `mariadbd` server instance reads and in what order, execute:

  Bash

  ```
  mariadbd --help --verbose
  ```

  Look for a line similar to: `Default options are read from the following files in the given order: /etc/my.cnf /etc/mysql/my.cnf ~/.my.cnf`

Modifying the Configuration File for Remote Access

1. **Open the File:** Use a text editor to open the primary configuration file identified (e.g., `/etc/mysql/my.cnf`).
2. **Locate `[mysqld]` Section:** Find the section starting with `[mysqld]`.
3. **Adjust Directives:**
   - If `skip-networking` is present and enabled (not commented out with `#`), comment it out or set it to `0`:Ini, TOML

     ```
     #skip-networking
     ```

     orIni, TOML

     ```
     skip-networking=0
     ```

   - If `bind-address = 127.0.0.1` (or another loopback/specific IP that's too restrictive) is present:
     - To listen on all available IPv4 interfaces: Comment it out entirely (`#bind-address = 127.0.0.1`) or set `bind-address = 0.0.0.0`.
     - To listen on a specific public IP address of your server: `bind-address = <your_server_public_ip>`.
     - Alternatively, to effectively disable binding to a specific address and listen on all, you can add `skip-bind-address`. Example changes:

```
[mysqld]
...
#skip-networking
#bind-address = 127.0.0.1
...
```

Or, to be explicit for listening on all interfaces if `bind-address` was previously restrictive:

```
[mysqld]
bind-address = 0.0.0.0
```

4. **Save and Restart:** Save the configuration file and restart the MariaDB server service.
   - See Starting and Stopping MariaDB for instructions.
5. **Verify Settings (Optional):** You can check the options `mariadbd` is effectively using by running:

```
./sql/mariadbd --print-defaults  # Adjust path to mariadbd if necessary
```

Look for the effective `bind-address` value or the absence of `skip-networking`. If multiple `[mysqld]` sections or `skip-bind-address` are used, the last specified prevailing value is typically what counts.

Granting User Privileges for Remote Connections

Configuring the server to listen for remote connections is only the first step. You must also grant privileges to user accounts to connect from specific remote hosts. MariaDB user accounts are defined as `'username'@'hostname'`.

1. **Connect to MariaDB:**

```
mariadb -u root -p
```

2. **View Existing Remote Users (Optional):**SQL

```
SELECT User, Host FROM mysql.user
WHERE Host <> 'localhost' AND Host <> '127.0.0.1' AND Host <> '::1';
```

3. **Grant Privileges:** Use the `GRANT` statement to allow a user to connect from a remote host or a range of hosts.
   - **Syntax Elements:**
     - Privileges (e.g., `ALL PRIVILEGES`, `SELECT, INSERT, UPDATE`)
     - Database/tables (e.g., `database_name.*` for all tables in a database, `*.*` for all databases)
     - Username
     - Host (IP address, hostname, or subnet with wildcards like `%`)
     - Password (using `IDENTIFIED BY 'password'`)
   - **Example: Grant `root`-like access from a specific LAN subnet:** It's highly discouraged to allow `root` access from all hosts (`'root'@'%'`) directly to the internet. Instead, restrict it to trusted networks if necessary.

     SQL

```
GRANT ALL PRIVILEGES ON *.* TO 'root'@'192.168.100.%'
  IDENTIFIED BY 'my-very-strong-password' WITH GRANT OPTION;
FLUSH PRIVILEGES;
```

     This allows the `root` user to connect from any IP address in the `192.168.100.x` subnet. Replace `'my-very-strong-password'` with a strong, unique password.

- For creating less privileged users or more granular permissions, see the GRANT documentation.

Configuring Your Firewall

Even if MariaDB is configured for remote access, a firewall on the server (software or hardware) might block incoming connections on MariaDB's port (default is `3306`).

- **RHEL/CentOS 7 Example (using `firewall-cmd`):**

  ```
  sudo firewall-cmd --add-port=3306/tcp --permanent
  sudo firewall-cmd --reload
  ```

  The first command adds the rule, the second makes it persist after reboots and applies the changes. Consult your OS/firewall documentation for specific commands.

Important Considerations and Reverting Changes

- **Security:** Opening MariaDB to remote connections, especially to the internet, increases security risks. Always use strong passwords, grant minimal necessary privileges, and restrict host access as much as possible. Consider using TLS/SSL for encrypted connections (see Secure Connections Overview).
- **Reverting:** To disable remote access and revert to a more secure local-only setup:
  1. Edit your MariaDB configuration file.
  2. Ensure `skip-networking` is not enabled (or is `0`).
  3. Set `bind-address = 127.0.0.1` explicitly, or remove any `skip-bind-address` directive if you previously added it to listen on all interfaces. The goal is to have `bind-address=127.0.0.1` as the effective setting.
  4. Restart the MariaDB server.
  5. Review and revoke any unnecessary remote `GRANT` privileges.

The initial version of this article was copied, with permission, from Remote_Clients_Cannot_Connect on 2012-10-30.

Getting Data Guide

This guide explains how to retrieve data from MariaDB using the `SELECT` statement, progressing from basic syntax to more involved queries. Learn to select specific columns, limit results, filter with `WHERE`, sort with `ORDER BY`, join tables, and use various helpful options and functions.

Setup: Creating and Populating Example Tables

To follow the examples, first create and populate the `books` and `authors` tables:

```
CREATE OR REPLACE TABLE books (
    isbn CHAR(20) PRIMARY KEY,
    title VARCHAR(50),
    author_id INT,
    publisher_id INT,
    year_pub CHAR(4),
    description TEXT
);

CREATE OR REPLACE TABLE authors (
    author_id INT AUTO_INCREMENT PRIMARY KEY,
    name_last VARCHAR(50),
    name_first VARCHAR(50),
    country VARCHAR(50)
);

INSERT INTO authors (name_last, name_first, country) VALUES
  ('Kafka', 'Franz', 'Czech Republic'),
  ('Dostoevsky', 'Fyodor', 'Russia');

INSERT INTO books (title, author_id, isbn, year_pub) VALUES
 ('The Trial', 1, '0805210407', '1995'),
 ('The Metamorphosis', 1, '0553213695', '1995'),
 ('America', 2, '0805210644', '1995'), -- Note: Original data had author_id 2 for 'America', Dostoevsky
is author_id 2.
 ('Brothers Karamozov', 2, '0553212168', ''),
 ('Crime & Punishment', 2, '0679420290', ''),
 ('Crime & Punishment', 2, '0553211757', ''),
 ('Idiot', 2, '0192834118', ''),
 ('Notes from Underground', 2, '067973452X', '');
```

Basic Data Retrieval

Selecting All Columns:

Use * to select all columns from a table.

```
SELECT * FROM books;
```

Output (example):

```
+------------+-----------------------+-----------+--------------+----------+-------------+
| isbn       | title                 | author_id | publisher_id | year_pub | description |
+------------+-----------------------+-----------+--------------+----------+-------------+
| 0192834118 | Idiot                 |         2 |         NULL |          | NULL        |
| 0553211757 | Crime & Punishment    |         2 |         NULL |          | NULL        |
... (other rows)
| 0805210644 | America               |         2 |         NULL | 1995     | NULL        |
+------------+-----------------------+-----------+--------------+----------+-------------+
8 rows in set (0.001 sec)
```

Selecting Specific Columns:

List the column names separated by commas.

```
SELECT isbn, title, author_id FROM books;
```

Output (example):

```
+------------+-----------------------+-----------+
| isbn       | title                 | author_id |
+------------+-----------------------+-----------+
| 0192834118 | Idiot                 |         2 |
| 0553211757 | Crime & Punishment    |         2 |
... (other rows)
+------------+-----------------------+-----------+
8 rows in set (0.001 sec)
```

Limiting the Number of Rows with `LIMIT`:

- To get the first `N` rows:

  ```
  SELECT isbn, title, author_id FROM books LIMIT 5;
  ```

  Output (example):

  ```
  +------------+--------------------+-----------+
  | isbn       | title              | author_id |
  +------------+--------------------+-----------+
  | 0192834118 | Idiot              |         2 |
  | 0553211757 | Crime & Punishment |         2 |
  | 0553212168 | Brothers Karamozov |         2 |
  | 0553213695 | The Metamorphosis  |         1 |
  | 0679420290 | Crime & Punishment |         2 |
  +------------+--------------------+-----------+
  5 rows in set (0.001 sec)
  ```

- To get `N` rows starting from an offset (offset is 0-indexed):SQL

  ```
  SELECT isbn, title, author_id FROM books LIMIT 5, 10; -- Skip 5 rows, show next 10 (or fewer if less
  remain)
  ```

  Output (example, assuming only 3 more rows exist after offset 5):

  ```
  +------------+-----------------------+-----------+
  | isbn       | title                 | author_id |
  +------------+-----------------------+-----------+
  | 067973452X | Notes from Underground |         2 |
  | 0805210407 | The Trial             |         1 |
  | 0805210644 | America               |         2 |
  +------------+-----------------------+-----------+
  3 rows in set (0.001 sec)
  ```

Filtering and Ordering Results

Filtering with `WHERE`:

Use the `WHERE` clause to specify conditions for row selection.

```
SELECT isbn, title
FROM books
WHERE author_id = 2
LIMIT 5;
```

Output (example):

```
+------------+------------------------+
| isbn       | title                  |
+------------+------------------------+
| 0192834118 | Idiot                  |
| 0553211757 | Crime & Punishment     |
| 0553212168 | Brothers Karamozov     |
| 0679420290 | Crime & Punishment     |
| 067973452X | Notes from Underground |
+------------+------------------------+
5 rows in set (0.000 sec)
```

Ordering with `ORDER BY`:

Use `ORDER BY column_name [ASC|DESC]` to sort the result set.

```
SELECT isbn, title
FROM books
WHERE author_id = 2
ORDER BY title ASC
LIMIT 5;
```

Output (example):

```
+------------+--------------------+
| isbn       | title              |
+------------+--------------------+
| 0805210644 | America            |
| 0553212168 | Brothers Karamozov |
| 0553211757 | Crime & Punishment |
| 0679420290 | Crime & Punishment |
| 0192834118 | Idiot              |
+------------+--------------------+
5 rows in set (0.001 sec)
```

- `ASC` (ascending) is the default order. `DESC` is for descending order.
- You can order by multiple columns: `ORDER BY col1 ASC, col2 DESC`.
- **Clause Order:** `SELECT ... FROM ... WHERE ... ORDER BY ... LIMIT ...`. MariaDB generally processes `WHERE`, then `ORDER BY`, then `LIMIT`.

Working with Multiple Tables (JOINs) and Functions

Joining Tables:

Use JOIN to combine rows from two or more tables based on a related column.

```
SELECT isbn, title, CONCAT(name_first, ' ', name_last) AS author
FROM books
JOIN authors USING (author_id) -- Assumes 'author_id' column exists in both tables
WHERE name_last = 'Dostoevsky'
ORDER BY title ASC
LIMIT 5;
```

Output (example):

```
+------------+--------------------+-------------------+
| isbn       | title              | author            |
+------------+--------------------+-------------------+
| 0805210644 | America            | Fyodor Dostoevsky |
| 0553212168 | Brothers Karamozov | Fyodor Dostoevsky |
| 0553211757 | Crime & Punishment | Fyodor Dostoevsky |
| 0679420290 | Crime & Punishment | Fyodor Dostoevsky |
| 0192834118 | Idiot              | Fyodor Dostoevsky |
+------------+--------------------+-------------------+
5 rows in set (0.00 sec)
```

- Alternative `JOIN` syntax: `... JOIN authors ON books.author_id = authors.author_id ...`. For more on joins, see the JOIN Syntax documentation or a "Basic Joins Guide".
- **`CONCAT(str1, str2, ...)`:** Concatenates strings.
- **`AS alias_name`:** Assigns an alias to an output column.

Pattern Matching with LIKE:

Use LIKE in the WHERE clause for pattern matching. % is a wildcard for zero or more characters.

```
SELECT isbn, title, CONCAT(name_first, ' ', name_last) AS author
FROM books
JOIN authors USING (author_id)
WHERE name_last LIKE 'Dostoevsk%'
ORDER BY title ASC
LIMIT 5;
```

Output (example, same as above if only Dostoevsky matches):

```
+------------+--------------------+-------------------+
| isbn       | title              | author            |
+------------+--------------------+-------------------+
| 0805210644 | America            | Fyodor Dostoevsky |
| 0553212168 | Brothers Karamozov | Fyodor Dostoevsky |
| 0553211757 | Crime & Punishment | Fyodor Dostoevsky |
| 0679420290 | Crime & Punishment | Fyodor Dostoevsky |
| 0192834118 | Idiot              | Fyodor Dostoevsky |
+------------+--------------------+-------------------+
5 rows in set (0.001 sec)
```

SELECT Statement Modifiers

Place these modifiers immediately after the `SELECT` keyword.

- **`ALL` vs `DISTINCT`:**
  - `ALL` (default): Returns all rows that meet the criteria.
  - `DISTINCT`: Returns only unique rows for the selected columns. If multiple identical rows are found for the specified columns, only the first one is displayed.

```
SELECT DISTINCT title
FROM books
JOIN authors USING (author_id)
WHERE name_last = 'Dostoevsky'
ORDER BY title;
```

Output (example, showing one "Crime & Punishment"):

```
+-----------------------+
| title                 |
+-----------------------+
| America               |
| Brothers Karamozov    |
| Crime & Punishment    |
| Idiot                 |
| Notes from Underground |
+-----------------------+
```

- `HIGH_PRIORITY`:

  Gives the `SELECT` statement higher priority over concurrent data modification statements (use with caution as it can impact write performance).

  SQL

```
SELECT DISTINCT HIGH_PRIORITY title
FROM books
JOIN authors USING (author_id)
WHERE name_last = 'Dostoevsky'
ORDER BY title;
```

- `SQL_CALC_FOUND_ROWS` and `FOUND_ROWS()`:

  To find out how many rows a query would have returned without a `LIMIT` clause, use `SQL_CALC_FOUND_ROWS` in your `SELECT` statement, and then execute `SELECT FOUND_ROWS()`; immediately after.

```
SELECT SQL_CALC_FOUND_ROWS isbn, title
FROM books
JOIN authors USING (author_id)
WHERE name_last = 'Dostoevsky'
ORDER BY title -- Order before limit to ensure consistent FOUND_ROWS() for a given query logic
LIMIT 5;
```

  Output (example for the first query):

```
+------------+-----------------------+
| isbn       | title                 |
+------------+-----------------------+
| 0805210644 | America               |
| 0553212168 | Brothers Karamozov    |
| 0553211757 | Crime & Punishment    |
| 0679420290 | Crime & Punishment    |
| 0192834118 | Idiot                 |
+------------+-----------------------+
5 rows in set (0.001 sec)
```

  Then, to get the total count:

```
SELECT FOUND_ROWS();
```

  Output (example, if 6 Dostoevsky books in total):

```
+--------------+
| FOUND_ROWS() |
+--------------+
|            6 |
+--------------+
1 row in set (0.000 sec)
```

  The value from `FOUND_ROWS()` is temporary and specific to the current session.

Basic SQL Statements Guide

This guide provides a quick overview of essential SQL statements in MariaDB, categorized by their function in data definition, data manipulation, and transaction control. Find brief descriptions and links to detailed documentation for each statement, along with a simple illustrative example sequence.

(If you need a basic tutorial on how to use the MariaDB database server and execute simple commands, see A MariaDB Primer. Also see Essential Queries Guide for examples of commonly-used queries.)

Defining How Your Data Is Stored

These statements are part of the SQL Data Definition Language - DDL.

CREATE DATABASE

Used to create a new, empty database.

DROP DATABASE

Used to completely destroy an existing database.

USE

Used to select a default database for subsequent statements.

CREATE TABLE

Used to create a new table, which is where your data is actually stored.

ALTER TABLE

Used to modify an existing table's definition (e.g., add/remove columns, change types).

DROP TABLE

Used to completely destroy an existing table and all its data.

DESCRIBE (or `DESC`)

Shows the structure of a table (columns, data types, etc.).

Manipulating Your Data

These statements are part of the SQL Data Manipulation Language - DML.

- **SELECT**: Used when you want to read (or select) your data from one or more tables.
- **INSERT**: Used when you want to add (or insert) new rows of data into a table.
- **UPDATE**: Used when you want to change (or update) existing data in a table.
- **DELETE**: Used when you want to remove (or delete) existing rows of data from a table.
- **REPLACE**: Works like `INSERT`, but if an old row in the table has the same value as a new row for a `PRIMARY KEY` or a `UNIQUE` index, the old row is deleted before the new row is inserted.
- **TRUNCATE TABLE**: Used to quickly remove all data from a table, resetting any `AUTO_INCREMENT` values. It is faster than `DELETE` without a `WHERE` clause for emptying a table.

Transactions

These statements are part of the SQL Transaction Control Language - TCL.

- **START TRANSACTION** (or `BEGIN`): Used to begin a new transaction, allowing multiple SQL statements to be treated as a single atomic unit.
- **COMMIT**: Used to save all changes made during the current transaction, making them permanent.
- **ROLLBACK**: Used to discard all changes made during the current transaction, reverting the database to its state before the transaction began.

A Simple Example Sequence

This example demonstrates several of the statements in action:

```
-- Create a new database
CREATE DATABASE mydb;

-- Select the new database to use
USE mydb;

-- Create a new table
CREATE TABLE mytable (
    id INT PRIMARY KEY,
    name VARCHAR(20)
);

-- Insert some data
INSERT INTO mytable VALUES (1, 'Will');
INSERT INTO mytable VALUES (2, 'Marry');
INSERT INTO mytable VALUES (3, 'Dean');

-- Select specific data
SELECT id, name FROM mytable WHERE id = 1;

-- Update existing data
UPDATE mytable SET name = 'Willy' WHERE id = 1;

-- Select all data to see changes
SELECT id, name FROM mytable;

-- Delete specific data
DELETE FROM mytable WHERE id = 1;

-- Select all data again
SELECT id, name FROM mytable;

-- Drop the database (removes the database and its tables)
DROP DATABASE mydb;
```

Common Query: Counting Rows

To count the number of records in a table:

```
SELECT COUNT(*) FROM mytable; -- Or SELECT COUNT(1) FROM mytable;
```

(Note: This query would typically be run on an existing table, for example, before it or its database is dropped.)

Basic SQL Debugging Guide

Designing Queries

Following a few conventions makes finding errors in queries a lot easier, especially when you ask for help from people who might know SQL, but know nothing about your particular schema. A query easy to read is a query easy to debug. Use whitespace to group clauses within the query. Choose good table and field aliases to add clarity, not confusion. Choose the syntax that supports the query's meaning.

Using Whitespace

A query hard to read is a query hard to debug. White space is free. New lines and indentation make queries easy to read, particularly when constructing a query inside a scripting language, where variables are interspersed throughout the query.

There is a syntax error in the following. How fast can you find it?

```
SELECT u.id, u.name, alliance.ally FROM users u JOIN alliance ON
(u.id=alliance.userId) JOIN team ON (alliance.teamId=team.teamId
WHERE team.teamName='Legionnaires' AND u.online=1 AND ((u.subscription='paid'
AND u.paymentStatus='current') OR u.subscription='free') ORDER BY u.name;
```

Here's the same query, with correct use of whitespace. Can you find the error faster?

```
SELECT
    u.id
    , u.name
    , alliance.ally
FROM
    users u
    JOIN alliance ON (u.id = alliance.userId)
    JOIN team ON (alliance.teamId = team.teamId
WHERE
    team.teamName = 'Legionnaires'
    AND u.online = 1
    AND (
        (u.subscription = 'paid' AND u.paymentStatus = 'current')
        OR
        u.subscription = 'free'
    )
ORDER BY
    u.name;
```

Even if you don't know SQL, you might still have caught the missing ')' following team.teamId.

The exact formatting style you use isn't so important. You might like commas in the select list to follow expressions, rather than precede them. You might indent with tabs or with spaces. Adherence to some particular form is not important. Legibility is the only goal.

Table and Field Aliases

Aliases allow you to rename tables and fields for use within a query. This can be handy when the original names are very long, and is required for self joins and certain subqueries. However, poorly chosen aliases can make a query harder to debug, rather than easier. Aliases should reflect the original table name, not an arbitrary string.

Bad:

```
SELECT *
FROM
    financial_reportQ_1 AS a
    JOIN sales_renderings AS b ON (a.salesGroup = b.groupId)
    JOIN sales_agents AS c ON (b.groupId = c.group)
WHERE
    b.totalSales > 10000
    AND c.id != a.clientId
```

As the list of joined tables and the `WHERE` clause grow, it becomes necessary to repeatedly look back to the top of the query to see to which table any given alias refers.

Better:

```
SELECT *
FROM
    financial_report_Q_1 AS frq1
    JOIN sales_renderings AS sr ON (frq1.salesGroup = sr.groupId)
    JOIN sales_agents AS sa ON (sr.groupId = sa.group)
WHERE
    sr.totalSales > 10000
    AND sa.id != frq1.clientId
```

Each alias is just a little longer, but the table initials give enough clues that anyone familiar with the database only need see the full table name once, and can generally remember which table goes with which alias while reading the rest of the query.

Placing JOIN Conditions

The manual warns against using the `JOIN` condition (that is, the ON clause) for restricting rows. Some queries, particularly those using implicit joins, take the opposite extreme - all join conditions are moved to the `WHERE` clause. In consequence, the table relationships are mixed with the business logic.

Bad:

```
SELECT *
FROM
    family,
    relationships
WHERE
    family.personId = relationships.personId
    AND relationships.relation = 'father'
```

Without digging through the WHERE clause, it is impossible to say what links the two tables.

Better:

```
SELECT *
FROM
    family
    JOIN relationships ON (family.personId = relationships.personId)
WHERE
    relationships.relation = 'father'
```

The relation between the tables is immediately obvious. The WHERE clause is left to limit rows in the result set.

Compliance with such a restriction negates the use of the comma operator to join tables. It is a small price to pay. Queries should be written using the explicit JOIN keyword anyway, and the two should never be mixed (unless you like rewriting all your queries every time a new version changes operator precedence).

Finding Syntax Errors

Syntax errors are among the easiest problems to solve. MariaDB provides an error message showing the exact point where the parser became confused. Check the query, including a few words before the phrase shown in the error message. Most syntax and parsing errors are obvious after a second look, but some are more elusive, especially when the error text seems empty, points to a valid keyword, or seems to error on syntax that appears exactly correct.

Interpreting the Empty Error

Most syntax errors are easy to interpret. The error generally details the exact source of the trouble. A careful look at the query, with the error message in mind, often reveals an obvious mistake, such as misspelled field names, a missing '`AND`', or an extra closing parenthesis. Sometimes the error is a little less helpful. A frequent, less-than-helpful message:

```
ERROR 1064: You have an error in your SQL syntax; check the manual that corresponds to your
MariaDB server version for the right syntax to use near ' ' at line 1
```

The empty ' ' can be disheartening. Clearly there is an error, but where? A good place to look is at the end of the query. The ' ' suggests that the parser reached the end of the statement while still expecting some syntax token to appear.

Check for missing closers, such as ' and):

```
SELECT * FROM someTable WHERE field = 'value
```

Look for incomplete clauses, often indicated by an exposed comma:

```
SELECT * FROM someTable WHERE field = 1 GROUP BY id,
```

Checking for Keywords

MariaDB allows table and field names and aliases that are also reserved words. To prevent ambiguity, such names must be enclosed in backticks (`):

```
SELECT * FROM actionTable WHERE `DELETE` = 1;
```

If the syntax error is shown near one of your identifiers, check if it appears on the reserved word list.

A text editor with color highlighting for SQL syntax helps to find these errors. When you enter a field name, and it shows up in the same color as the SELECT keyword, you know something is amiss. Some common culprits:

- DESC is a common abbreviation for “description” fields. It means “descending” in a MariaDB ORDER clause.
- DATE, TIME, and TIMESTAMP are all common field names. They are also field types.
- ORDER appears in sales applications. MariaDB uses it to specify sorting for results.

Some keywords are so common that MariaDB makes a special allowance to use them unquoted. My advice: don’t. If it’s a keyword, quote it.

Version Specific Syntax

As MariaDB adds new features, the syntax must change to support them. Most of the time, old syntax will work in newer versions of MariaDB. One notable exception is the change in precedence of the comma operator relative to the JOIN keyword in version 5.0. A query that used to work, such as

```
SELECT * FROM a, b JOIN c ON a.x = c.x;
```

will now fail.

More common, however, is an attempt to use new syntax in an old version. Web hosting companies are notoriously slow to upgrade MariaDB, and you may find yourself using a version several years out of date. The result can be very frustrating when a query that executes flawlessly on your own workstation, running a recent installation, fails completely in your production environment.

This query fails in any version of MySQL prior to 4.1, when subqueries were added to the server:

```
SELECT * FROM someTable WHERE someId IN (SELECT id FROM someLookupTable);
```

This query fails in some early versions of MySQL, because the JOIN syntax did not originally allow an ON clause:

```
SELECT * FROM tableA JOIN tableB ON tableA.x = tableB.y;
```

Always check the installed version of MariaDB, and read the section of the manual relevant for that version. The manual usually indicates exactly when particular syntax became available for use.

MariaDB String Functions Guide

MariaDB has many built-in functions that can be used to manipulate strings of data. With these functions, one can format data, extract certain characters, or use search expressions. Good developers should be aware of the string functions that are available. Therefore, in this article we will go through several string functions, grouping them by similar features, and provide examples of how they might be used.

Formatting

There are several string functions that are used to format text and numbers for nicer display. A popular and very useful function for pasting together the contents of data fields with text is the CONCAT() function. As an example, suppose that a table called contacts has a column for each sales contact's first name and another for the last name. The following SQL statement would put them together:

```
SELECT CONCAT(name_first, ' ', name_last)
AS Name
FROM contacts;
```

This statement will display the first name, a space, and then the last name together in one column. The AS clause will change the column heading of the results to Name.

A less used concatenating function is CONCAT_WS(). It will put together columns with a separator between each. This can be useful when making data available for other programs. For instance, suppose we have a program that will import data, but it requires the fields to be separated by vertical bars. We could just export the data, or we could use a SELECT statement like the one that follows in conjunction with an interface written with an API language like Perl:

```
SELECT CONCAT_WS('|', col1, col2, col3)
FROM table1;
```

The first element above is the separator. The remaining elements are the columns to be strung together.

If we want to format a long number with commas every three digits and a period for the decimal point (e.g., 100,000.00), we can use the function FORMAT() like so:

```
SELECT CONCAT('$', FORMAT(col5, 2))
FROM table3;
```

In this statement, the CONCAT() will place a dollar sign in front of the numbers found in the `col5` column, which are formatted with commas by FORMAT(). The `2` within the FORMAT() stipulates two decimal places.

Occasionally, one will want to convert the text from a column to either all upper-case letters or all lower-case letters. In the example that follows, the output of the first column is converted to upper-case and the second to lower-case:

```
SELECT UCASE(col1),
LCASE(col2)
FROM table4;
```

When displaying data in forms, it's sometimes useful to pad the data displayed with zeros or dots or some other filler. This can be necessary when dealing with VARCHAR columns where the width varies to help the user to see the column limits. There are two functions that may be used for padding: LPAD() and RPAD().

```
SELECT RPAD(part_nbr, 8, '.') AS 'Part Nbr.',
LPAD(description, 15, '_') AS Description
FROM catalog;
```

In this SQL statement, dots are added to the right end of each part number. So a part number of "H200" will display as "H200….", but without the quotes. Each part's description will have under-scores preceding it. A part with a description of "brass hinge" will display as "brass hinge".

If a column is a CHAR data-type, a fixed width column, then it may be necessary to trim any leading or trailing spaces from displays. There are a few functions to accomplish this task. The LTRIM() function will eliminate any leading spaces to the left. So "`H200`" becomes "`H200`". For columns with trailing spaces, spaces on the right, RTRIM() will work: "`H500`" becomes "`H500`". A more versatile trimming function, though, is TRIM(). With it one can trim left, right or both. Below are a few examples:

```
SELECT TRIM(LEADING '.' FROM col1),
TRIM(TRAILING FROM col2),
TRIM(BOTH '_' FROM col3),
TRIM(col4)
FROM table5;
```

In the first TRIM() clause, the padding component is specified; the leading dots are to be trimmed from the output of `col1`. The trailing spaces are trimmed off of `col2`—space is the default. Both leading and trailing under-scores are trimmed from `col3` above. Unless specified, BOTH is the default. So leading and trailing spaces are trimmed from `col4` in the statement here.

Extracting

When there is a need to extract specific elements from a column, MariaDB has a few functions that can help. Suppose a column in the table contacts contains the telephone numbers of sales contacts, including the area-codes, but without any dashes or parentheses. The area-code of each could be extracted for sorting with the LEFT() and the telephone number with the RIGHT() function.

```
SELECT LEFT(telephone, 3) AS area_code,
RIGHT(telephone, 7) AS tel_nbr
FROM contacts
ORDER BY area_code;
```

In the LEFT() function above, the column telephone is given along with the number of characters to extract, starting from the first character on the left in the column. The RIGHT() function is similar, but it starts from the last character on the right, counting left to capture, in this statement, the last seven characters. In the SQL statement above,

area_code is reused to order the results set. To reformat the telephone number, it are necessary to use the SUBSTRING() function.

```
SELECT CONCAT('(', LEFT(telephone, 3), ') ',
SUBSTRING(telephone, 4, 3), '-',
MID(telephone, 7)) AS 'Telephone Number'
FROM contacts
ORDER BY LEFT(telephone, 3);
```

In this SQL statement, the CONCAT() function is employed to assemble some characters and extracted data to produce a common display for telephone numbers (e.g., (504) 555-1234). The first element of the CONCAT() is an opening parenthesis. Next, a LEFT() is used to get the first three characters of telephone, the area-code. After that a closing parenthesis, along with a space is added to the output. The next element uses the SUBSTRING() function to extract the telephone number's prefix, starting at the fourth position, for a total of three characters. Then a dash is inserted into the display. Finally, the function MID() extracts the remainder of the telephone number, starting at the seventh position. The functions MID() and SUBSTRING() are interchangeable and their syntax are the same. By default, for both functions, if the number of characters to capture isn't specified, then it's assumed that the remaining ones are to be extracted.

Manipulating

There are a few functions in MariaDB that can help in manipulating text. One such function is REPLACE(). With it every occurrence of a search parameter in a string can be replaced. For example, suppose we wanted to replace the title *Mrs.* with *Ms.* in a column containing the person's title, but only in the output. The following SQL would do the trick:

```
SELECT CONCAT(REPLACE(title, 'Mrs.', 'Ms.'),
' ', name_first, ' ', name_last) AS Name
FROM contacts;
```

We're using the ever handy CONCAT() function to put together the contact's name with spaces. The REPLACE() function extracts each title and replaces *Mrs.* with *Ms.*, where applicable. Otherwise, for all other titles, it displays them unchanged.

If we want to insert or replace certain text from a column (but not all of its contents), we could use the INSERT() function in conjunction with the LOCATE() function. For example, suppose another contacts table has the contact's title and full name in one column. To change the occurrences of Mrs. to Ms., we could not use REPLACE() since the title is embedded in this example. Instead, we would do the following:

```
SELECT INSERT(name, LOCATE(name, 'Mrs.'), 4, 'Ms.')
FROM contacts;
```

The first element of the INSERT() function is the column. The second element which contains the LOCATE() is the position in the string that text is to be inserted. The third element is optional; it states the number of characters to overwrite. In this case, Mrs. which is four characters is overwritten with Ms. (the final element), which is only three. Incidentally, if 0 is specified, then nothing is overwritten, text is inserted only. As for the LOCATE() function, the first element is the column and the second the search text. It returns the position within the column where the text is found. If it's not found, then 0 is returned. A value of 0 for the position in the INSERT() function negates it and returns the value of name unchanged.

On the odd chance that there is a need to reverse the content of a column, there's the REVERSE() function. You would just place the column name within the function. Another minor function is the REPEAT() function. With it a string may be repeated in the display:

```
SELECT REPEAT(col1, 2)
FROM table1;
```

The first component of the function above is the string or column to be repeated. The second component states the number of times it's to be repeated.

Expression Aids

The function CHAR_LENGTH() is used to determine the number of characters in a string. This could be useful in a situation where a column contains different types of information of specific lengths. For instance, suppose a column in a table for a college contains identification numbers for students, faculty, and staff. If student identification numbers have eight characters while others have less, the following will count the number of student records:

```
SELECT COUNT(school_id)
AS 'Number of Students'
FROM table8
WHERE CHAR_LENGTH(school_id)=8;
```

The COUNT() function above counts the number of rows that meet the condition of the `WHERE` clause.

In a SELECT statement, an ORDER BY clause can be used to sort a results set by a specific column. However, if the column contains IP addresses, a simple sort may not produce the desired results:

```
SELECT ip_address
FROM computers WHERE server='Y'
ORDER BY ip_address LIMIT 3;

+-------------+
| ip_address  |
+-------------+
| 10.0.1.1    |
| 10.0.11.1   |
| 10.0.2.1    |
+-------------+
```

In the limited results above, the IP address 10.0.2.1 should be second. This happens because the column is being sorted lexically and not numerically. The function INET_ATON() will solve this sorting problem.

```
SELECT ip_address
FROM computers WHERE server='Y'
ORDER BY INET_ATON(ip_address) LIMIT 3;
```

Basically, the INET_ATON() function will convert IP addresses to regular numbers for numeric sorting. For instance, if we were to use the function in the list of columns in a SELECT statement, instead of the `WHERE` clause, the address 10.0.1.1 would return 167772417, 10.0.11.1 will return 167774977, and 10.0.2.1 the number 167772673. As a complement to INET_ATON(), the function INET_NTOA() will translate these numbers back to their original IP addresses.

MariaDB is fairly case insensitive, which usually is fine. However, to be able to check by case, the STRCMP() function can be used. It converts the column examined to a string and makes a comparison to the search parameter.

```
SELECT col1, col2
FROM table6
WHERE STRCMP(col3, 'text')=0;
```

If there is an exact match, the function STRCMP() returns 0. So if `col3` here contains "Text", it won't match. Incidentally, if `col3` alphabetically is before the string to which it's compared, a `-1` are returned. If it's after it, a `1` is returned.

When you have list of items in one string, the SUBSTRING_INDEX() can be used to pull out a sub-string of data. As an example, suppose we have a column which has five elements, but we want to retrieve just the first two elements. This SQL statement will return them:

```
SELECT SUBSTRING_INDEX(col4, '|', 2)
FROM table7;
```

The first component in the function above is the column or string to be picked apart. The second component is the delimiter. The third is the number of elements to return, counting from the left. If we want to grab the last two elements, we would use a negative two to instruct MariaDB to count from the right end.

Conclusion

There are more string functions available in MariaDB. A few of the functions mentioned here have aliases or close alternatives. There are also functions for converting between ASCII, binary, hexi-decimal, and octal strings. And there are also string functions related to text encryption and decryption that were not mentioned. However, this article has given you a good collection of common string functions that will assist you in building more powerful and accurate SQL statements.

Restoring Data from Dump Files Guide

This guide explains how to restore your MariaDB data from backup files created with `mariadb-dump`. Learn the basic restoration process using the `mariadb` client and a specific technique for selectively restoring a single table while minimizing data loss on other tables.

It's important to understand that `mariadb-dump` is used for creating backup (dump) files, while the `mariadb` client utility is used for restoring data from these files. The dump file contains SQL statements that, when executed, recreate the database structure and/or data.

Basic Restoration Process

To restore a dump file, you direct the `mariadb` client to execute the SQL statements contained within the file.

```
mariadb --user your_username --password < /path/to/your/backupfile.sql
```

- Replace `your_username` with your MariaDB username and `/path/to/your/backupfile.sql` with the actual path to your dump file.
- You will be prompted for the password for `your_username`.
- The `<` symbol is a standard input (STDIN) redirect, feeding the contents of `backupfile.sql` to the `mariadb` client.
- Often, the dump file itself contains `CREATE DATABASE IF NOT EXISTS` and `USE database_name;` statements, so a specific database doesn't always need to be named on the command line during restore. If your dump file restores to a specific database, ensure that user has permissions to it. If the dump file does *not* specify a database, you might need to create the database first and then run:

  ```
  mariadb --user your_username --password your_database_name < /path/to/your/backupfile.sql
  ```

Important Considerations Before Restoring

- **Data Overwriting:** Restoring a dump file will execute the SQL statements within it. If the dump file contains `DROP TABLE` and `CREATE TABLE` statements (common for full backups), existing tables with the same names will be dropped and recreated, leading to loss of any data added or changed since the backup was made.
- **Backup Age:** If your dump file is several days old, restoring it entirely could revert all data in the affected tables/databases to that older state. This can be disastrous if only a small portion of data was lost and the rest has been actively updated.

Always ensure you understand the contents of the dump file and the potential impact before initiating a restore, especially on a production system. Consider testing the restore on a non-production environment first if possible.

Restoring a Single Table Selectively

If only one table has been lost or corrupted and your backup file contains an entire database (or multiple tables), a full restore might overwrite recent, valid data in other tables. Here's a method to restore only a specific table using a temporary user with restricted privileges:

1. **Create a Temporary User:** Create a MariaDB user specifically for this restore operation.
2. **Grant Limited Privileges:**
   - Grant this temporary user the minimal privileges needed for the dump file to execute up to the point of restoring your target table. This might be `SELECT` on all tables in the database if the dump file checks other tables, or simply the ability to `USE` the database.
   - Then, grant `ALL PRIVILEGES` (or specific necessary privileges like `CREATE`, `DROP`, `INSERT`, `SELECT`) *only* on the specific table you want to restore.

   Example SQL to create a temporary user and grant permissions (replace placeholders):

   ```
   -- Connect to MariaDB as an administrative user (e.g., root)
   CREATE USER 'admin_restore_temp'@'localhost' IDENTIFIED BY 'its_very_secure_pwd';

   -- Grant general SELECT on the database (might be needed if dump file structure requires it)
   -- Or, if not needed, ensure the user can at least USE the database.
   GRANT SELECT ON your_database_name.* TO 'admin_restore_temp'@'localhost';

   -- Grant full privileges ONLY on the table to be restored
   GRANT ALL PRIVILEGES ON your_database_name.table_to_restore TO 'admin_restore_temp'@'localhost';

   FLUSH PRIVILEGES;
   ```

3. Restore Using the Temporary User and `--force`:

   Use the mariadb client with the temporary user and the –force option. The –force option tells MariaDB to continue executing statements in the dump file even if some SQL errors occur. Errors will occur for operations on tables where admin_restore_temp lacks permissions, but operations on table_to_restore (where permissions were granted) should succeed.

   Bash

   ```
   mariadb --user admin_restore_temp --password --force your_database_name <
   /path/to/your/fulldumpfile.sql
   ```

   You will be prompted for the password of `admin_restore_temp`.

4. **Verify Restoration:** Check that `table_to_restore` has been correctly restored.
5. **Clean Up:** Drop the temporary user once the restoration is confirmed:

   ```
   DROP USER 'admin_restore_temp'@'localhost';
   ```

This method helps to isolate the restore operation to the intended table, protecting other data from being inadvertently reverted to an older state.

Changing Times in MariaDB

This guide explores MariaDB functions for performing calculations and modifications on date and time values. Learn to use functions like `DATE_ADD`, `DATE_SUB`, `TIME_TO_SEC`, and `SEC_TO_TIME` to accurately add or subtract intervals and manage date/time changes that cross midnight or month/year boundaries.

(For foundational knowledge on date and time data types and basic retrieval, please refer to the "Date and Time Handling Guide".)

Calculating Time Across Midnight

When adding hours to a `TIME` value, calculations might exceed 24 hours. For example, if a task is entered at 23:00 and is promised 2 hours later, a simple addition can be problematic.

Consider an `INSERT` statement for a `tickets` table with `entered` and `promised` `TIME` columns:

```
-- Example: Calculating a promised time 2 hours (7200 seconds) from current time
INSERT INTO tickets (client_id, urgency, trouble, ticket_date, entered, promised)
VALUES ('some_client', 'ASAP', 'Issue details',
        CURDATE(), CURTIME(),
        SEC_TO_TIME(TIME_TO_SEC(CURTIME()) + 7200));
```

- `TIME_TO_SEC(time)` converts a time value to seconds.
- `SEC_TO_TIME(seconds)` converts seconds back to a time format (`HHH:MM:SS`).

If `CURTIME()` is `23:00:00` (82,800 seconds), `82800 + 7200 = 90000` seconds. `SEC_TO_TIME(90000)` would result in `25:00:00`. While MariaDB can store this, it doesn't represent a standard clock time for the next day.

Modulo Arithmetic for Time Rollover:

To handle time wrapping around the 24-hour clock (86,400 seconds in a day) for TIME columns, use the modulo operator (%):

```
-- Corrected calculation for 'promised' TIME, wraps around 24 hours
SEC_TO_TIME((TIME_TO_SEC(CURTIME()) + 7200) % 86400)
```

If current time is 23:00, `(82800 + 7200) % 86400` becomes `90000 % 86400`, which is `3600` seconds. `SEC_TO_TIME(3600)` correctly results in `01:00:00`.

Tracking Date Changes with Time: Using `DATETIME`

The modulo arithmetic above gives the correct time of day but doesn't indicate if the promised time falls on the next calendar day. For calculations where the date might change, it's essential to use `DATETIME` (or `TIMESTAMP`) data types.

If your table initially used separate `DATE` and `TIME` columns (e.g., `ticket_date`, `entered_time`, `promised_time`), you would typically alter the table to use `DATETIME` columns (e.g., `entered_datetime`, `promised_datetime`) to store both date and time information accurately. This often involves:

1. Adding new `DATETIME` columns.
2. Populating them by combining the old date and time columns (e.g., using `CONCAT(ticket_date, ' ', entered_time)`).
3. Dropping the old separate date and time columns. *(Always back up your data before such structural changes.)*

With `DATETIME` columns, `NOW()` can be used to get the current date and time.

Adding Durations with `DATE_ADD`

The `DATE_ADD(date, INTERVAL expr unit)` function is the most robust way to add a duration to a date, time, or datetime value. It correctly handles rollovers across days, months, and years.

- `date`: A `DATE`, `DATETIME`, or `TIME` value.
- `expr`: The value of the interval to add.
- `unit`: The unit of the interval (e.g., `HOUR`, `MINUTE`, `DAY`, `MONTH`, `YEAR`, etc.).

Adding Hours (handles date change):

If entered and promised are DATETIME columns:

```
INSERT INTO tickets (client_id, urgency, trouble, entered, promised)
VALUES ('some_client', 'ASAP', 'Issue details',
        NOW(),
        DATE_ADD(NOW(), INTERVAL 2 HOUR));
```

If `NOW()` is `2025-06-03 23:00:00`, `promised` will correctly be `2025-06-04 01:00:00`.

Adding Combined Hours and Minutes:

Use HOUR_MINUTE as the unit. The expr is a string 'hours:minutes'.

```
-- Add 2 hours and 30 minutes
DATE_ADD(NOW(), INTERVAL '2:30' HOUR_MINUTE)
```

If `NOW()` is `2025-06-03 23:00:00`, this results in `2025-06-04 01:30:00`.

Date Calculations Across Months and Years with `DATE_ADD`

`DATE_ADD` also correctly handles date changes across month and year boundaries, including leap years.

Adding Days:

```
-- Add 5 days
DATE_ADD(NOW(), INTERVAL 5 DAY)
```

If `NOW()` is `2025-02-27`, this would result in `2025-03-04` (assuming 2025 is not a leap year).

Adding Combined Days and Hours:

Use DAY_HOUR as the unit. The expr is a string 'days hours'.

```
-- Add 2 days and 6 hours
DATE_ADD(NOW(), INTERVAL '2 6' DAY_HOUR)
```

Adding Combined Years and Months:

Use YEAR_MONTH as the unit. The expr is a string 'years-months'.

```
-- Add 1 year and 2 months
DATE_ADD(NOW(), INTERVAL '1-2' YEAR_MONTH) -- Note: Original text used '1 2', '1-2' is common for
YEAR_MONTH
```

If `NOW()` is `2025-09-15 23:00:00`, this results in `2026-11-15 23:00:00`. This type of interval typically does not affect the day or time components directly, only the year and month.

Subtracting Durations

Using DATE_ADD with a Negative Interval:

You can subtract durations by providing a negative value for expr.

```
-- Subtract 5 days
DATE_ADD(NOW(), INTERVAL -5 DAY)
```

Using DATE_SUB(date, INTERVAL expr unit):

This function is specifically for subtracting durations.

```
-- Subtract 5 days
DATE_SUB(NOW(), INTERVAL 5 DAY)
```

Note: With `DATE_SUB`, `expr` is positive for subtraction. A negative `expr` would result in addition.

System & Status Variables Guide

System variables and status variables serve two distinct roles in MariaDB: System variables are the “knobs” you turn to change how the server behaves, while status variables are the “gauges” you watch to see how the server is performing.

Because MariaDB is modular, these variables are often grouped by their specific functional area or plugin.

What you do with System Variables

System variables are configuration settings. You use them to define the environment, set resource limits, and tune performance.

- **Configuration & Tuning:** You modify these to optimize the server for your workload. For example, you might increase `innodb_buffer_pool_size` to allow the database to cache more data in memory, reducing disk I/O.
- **Controlling Behavior:** You use them to toggle features on or off. Setting `read_only` to `1` ensures no data can be modified (useful for maintenance or replicas).
- **Enforcing Constraints:** You set limits to prevent resource exhaustion. For example, `max_connections` prevents the server from being overwhelmed by too many simultaneous users.
- **Session Personalization:** Many variables can be set at the Session level. This means you can change how the server behaves just for your current connection – like changing the `sql_mode` to be more or less strict – without affecting other users.

What you use Status Variables for

Status variables are read-only counters and metrics. You use them to monitor the health and activity of the server.

- **Performance Monitoring:** You check status variables to see if your system tuning is working. If you see high numbers for `Select_full_join`, it tells you that your queries are missing indexes.
- **Health Checks:** You use them to identify bottlenecks. If `Aborted_connects` is high, you might have network issues or a client with the wrong password attempting to connect repeatedly.
- **Resource Tracking:** They tell you how much of your allocated resources are actually being used. Comparing `Max_used_connections` against your system variable `max_connections` helps you decide if you need to scale up.
- **Capacity Planning:** By monitoring variables like `Bytes_sent` and `Bytes_received` over time, you can forecast when you will need to upgrade your hardware or network bandwidth.

Comparison at a Glance

Feature	System Variables	Status Variables
Analogy	Steering wheel / Gas pedal	Speedometer / Fuel gauge
Action	Set (change the value)	View (read the value)
Purpose	Control and configuration	Monitoring and diagnostics
SQL Statement	`SET GLOBAL ...` or `SET SESSION ...`	`SHOW STATUS ...`

Pages Documenting Variables

Here is the comprehensive list of pages that document variables.

Core Server Variables

- Server System Variables (The main list for general server configuration)
- Server Status Variables (Real-time monitoring metrics)
- Performance Schema System Variables

Storage Engine Specific Variables

- Aria System Variables
- Aria Status Variables
- InnoDB System Variables
- MyISAM System Variables
- CONNECT System Variables
- Spider System Variables
- Spider Status Variables

Replication & Performance Variables

- Replication and Binary Log System Variables
- Replication and Binary Log Status Variables
- Thread Pool System and Status Variables

Plugin Specific Variables

- Audit Plugin Options and System Variables
- Audit Plugin Status Variables
- Encryption Plugin System Variables (for instance, File Key Management)

Index / Master List

- Full list of MariaDB options, system and status variables
  Note: This page acts as a directory that links back to the detailed pages above.

Making Backups with mariadb-dump Guide

This guide explains how to use the `mariadb-dump` utility to create essential backup (dump) files of your MariaDB data. Learn to effectively back up all databases, specific databases, or individual tables, ensuring your data is protected and can be restored when needed.

About `mariadb-dump`

`mariadb-dump` is a command-line utility included with MariaDB for creating logical backups of your databases. It was previously known as `mysqldump`, which often still works as a symbolic link.

Key Advantages:

- **No Server Shutdown:** Backups can be performed while the MariaDB server is running.
- **SQL Output:** It generates a `.sql` file (a "dump file") containing SQL statements (`CREATE TABLE`, `INSERT`, etc.) necessary to reconstruct the databases and data.

All `mariadb-dump` commands are executed from your system's command-line shell, not within the `mariadb` client.

Backing Up All Databases

To export all databases managed by your MariaDB server:

```
mariadb-dump --user=admin_backup --password --lock-tables --all-databases >
/data/backup/dbs_alldatabases.sql
```

- `--user=admin_backup`: Specifies the MariaDB user performing the backup (this user needs appropriate privileges, typically at least `SELECT` and `LOCK TABLES`).
- `--password`: Prompts for the user's password. For use in scripts where prompting is not possible, you can use `--password=yourpassword` (note the absence of a space and the security implication of having the password in a script or command history).
- `--lock-tables` (or `-x`): Locks all tables across all databases before starting the backup to ensure data consistency. The lock is released once the dump is complete for each table. For transactional tables like InnoDB, using `--single-transaction` is often preferred as it provides a consistent snapshot without prolonged locking of all tables.
- `--all-databases` (or `-A`): Specifies that all databases should be dumped.
- `> /data/backup/dbs_alldatabases.sql`: Redirects the output (the SQL statements) to the specified file. Ensure the path exists and the user running the command has write permissions.

Commonly Used Option for Efficiency:

- `--extended-insert` (or `-e`): Creates `INSERT` statements that include multiple rows per statement. This generally results in a smaller dump file and faster restores. This option is often enabled by default but can be explicitly stated.

Example with long options and password in script:

```
mariadb-dump --user=admin_backup --password=yoursecurepassword --lock-tables --extended-insert --all-
databases > /data/backup/dbs_alldatabases.sql
```

Backing Up a Single Database

Backing up databases individually can result in smaller, more manageable dump files and allow for more flexible backup schedules.

```
mariadb-dump --user=admin_backup --password --lock-tables --extended-insert --databases
your_database_name > /data/backup/your_database_name.sql
```

- `--databases` (or `-B`): Followed by the name of the database to dump.
- To back up multiple specific databases, list their names separated by spaces after the `--databases` option:

```
mariadb-dump --user=admin_backup --password --lock-tables --extended-insert --databases db1_name
db2_name > /data/backup/selected_databases.sql
```

Backing Up Specific Tables

For very large databases, or if only certain tables change frequently, you might back up individual tables.

```
mariadb-dump --user=admin_backup --password --lock-tables --extended-insert your_database_name
table_name1 table_name2 > /data/backup/your_database_name_selected_tables.sql
```

- First, specify the database name (`your_database_name`).
- Then, list one or more table names (`table_name1` , `table_name2`) separated by spaces.
- Note that the `--databases` option is *not* used when dumping specific tables in this manner.

Important Considerations and Best Practices

- **User Privileges:** The MariaDB user specified with `--user` needs at least `SELECT` privileges for the tables being dumped. `LOCK TABLES` privilege is needed if using `--lock-tables` . `RELOAD` or `FLUSH_TABLES` might be needed for options like `--flush-logs` or `--master-data` . For `--single-transaction` , `PROCESS` and `RELOAD` might be required. A user with global `SELECT` , `LOCK TABLES` , `SHOW VIEW` , `EVENT` , and `TRIGGER` privileges is often used for backups.
- **Consistency with InnoDB:** For databases primarily using InnoDB tables, consider using the `--single-transaction` option instead of `--lock-tables` . This option starts a transaction before dumping and reads data from a consistent snapshot without locking the tables for extended periods, allowing concurrent reads and writes.Bash

  ```
  mariadb-dump --user=admin_backup --password --single-transaction --extended-insert --databases
  your_innodb_database > /data/backup/your_innodb_database.sql
  ```
- **Practice Makes Perfect:** `mariadb-dump` is powerful but can have many options. Practice using it on a test database or server to become comfortable with its usage and to verify that your backup strategy works as expected.
- **Test Your Backups:** Regularly test your backup files by restoring them to a non-production environment to ensure they are valid and can be used for recovery.
- **Restoration:** To learn how to restore data from these dump files, see the “Data Restoration Guide”.
- **Security:** Store backup files in a secure location. If passwords are included in scripts, ensure the script files have restricted permissions.

A MariaDB Primer Guide

This primer offers a quick jump-start for beginners using an existing MariaDB database via the `mariadb` command-line client. Learn how to log in, understand basic database concepts, and perform essential SQL operations like creating tables, inserting data, and retrieving or modifying records.

Logging into MariaDB

To begin, log into your MariaDB server from your system’s command-line:

```
mariadb -u user_name -p -h ip_address db_name
```

- Replace `user_name` with your MariaDB username.
- Replace `ip_address` with the hostname or IP address of your MariaDB server. If you are accessing MariaDB from the same server you're logged into (locally = `localhost`), you can usually omit the `-h ip_address` part.
- Replace `db_name` with the name of the database you wish to access (for instance, `test`). Some setups may have a `test` database by default; others might not, or it might have been removed (for instance, by `mariadb-secure-installation`). If unsure, or if you want to connect without selecting a specific database initially, you can omit `db_name`.

You are prompted to enter your password. If your login is successful, you see a prompt similar to this:

```
MariaDB [test]>
```

"MariaDB" indicates you are connected to a MariaDB server. The name within the brackets (for instance, `test`) is your current default database. If no database was specified or successfully connected to, it shows `[(none)]`.

Understanding Database Basics and Setup

SQL (Structured Query Language): This is the language used to interact with MariaDB. An SQL statement that requests data is called a query.

Tables: Databases store information in tables, which are structured like spreadsheets with rows and columns, but are much more efficient for data management.

Example Setup:

If the test database is empty or doesn't exist, you can run the following SQL statements to create and populate tables for the examples in this primer. Copy and paste these into the mariadb client prompt.

```
CREATE DATABASE IF NOT EXISTS test;
USE test;

CREATE TABLE IF NOT EXISTS books (
  BookID INT NOT NULL PRIMARY KEY AUTO_INCREMENT,
  Title VARCHAR(100) NOT NULL,
  SeriesID INT,
  AuthorID INT
);

CREATE TABLE IF NOT EXISTS authors (
  id INT NOT NULL PRIMARY KEY AUTO_INCREMENT
  -- You would typically add more columns like name, etc.
);

CREATE TABLE IF NOT EXISTS series (
  id INT NOT NULL PRIMARY KEY AUTO_INCREMENT
  -- You would typically add more columns like series_name, etc.
);

INSERT INTO books (Title, SeriesID, AuthorID) VALUES
  ('The Fellowship of the Ring', 1, 1),
  ('The Two Towers', 1, 1),
  ('The Return of the King', 1, 1),
  ('The Sum of All Men', 2, 2),
  ('Brotherhood of the Wolf', 2, 2),
  ('Wizardborn', 2, 2),
  ('The Hobbbit', 0, 1); -- Note: "Hobbbit" is intentionally misspelled for a later example
```

- **Semicolons (`;`):** The `mariadb` client allows complex SQL statements over multiple lines. It sends the statement to the server for execution only after you type a semicolon (`;`) and press [Enter].

Exploring Your Database Structure

Listing Tables:

To see the tables in your current database:

```
SHOW TABLES;
```

Output (example):

```
+----------------+
| Tables_in_test |
+----------------+
| authors        |
| books          |
| series         |
+----------------+
3 rows in set (0.00 sec)
```

Describing a Table:

To get information about the columns in a table (like their names and types):

```
DESCRIBE books;
```

Output (example):

```
+----------+--------------+------+-----+---------+----------------+
| Field    | Type         | Null | Key | Default | Extra          |
+----------+--------------+------+-----+---------+----------------+
| BookID   | int(11)      | NO   | PRI | NULL    | auto_increment |
| Title    | varchar(100) | NO   |     | NULL    |                |
| SeriesID | int(11)      | YES  |     | NULL    |                |
| AuthorID | int(11)      | YES  |     | NULL    |                |
+----------+--------------+------+-----+---------+----------------+
```

The `Field` column lists the column names, which you'll need to retrieve specific data.

Retrieving Data (SELECT)

To retrieve data from a table, use the `SELECT` statement.

```
SELECT * FROM books;
```

- The asterisk (`*`) is a wildcard meaning "all columns." **Output (example):**

```
+--------+---------------------------+----------+----------+
| BookID | Title                     | SeriesID | AuthorID |
+--------+---------------------------+----------+----------+
|      1 | The Fellowship of the Ring |        1 |        1 |
|      2 | The Two Towers             |        1 |        1 |
|      3 | The Return of the King     |        1 |        1 |
|      4 | The Sum of All Men         |        2 |        2 |
|      5 | Brotherhood of the Wolf    |        2 |        2 |
|      6 | Wizardborn                 |        2 |        2 |
|      7 | The Hobbbit                |        0 |        1 |
+--------+---------------------------+----------+----------+
7 rows in set (0.00 sec)
```

Adding Data (INSERT)

To add new rows to a table, use the `INSERT` statement.

```
INSERT INTO books (Title, SeriesID, AuthorID)
VALUES ("Lair of Bones", 2, 2);
```

- After `INSERT INTO table_name`, list the columns you are providing data for in parentheses.
- The `VALUES` keyword is followed by a list of values in parentheses, in the same order as the listed columns.
  Output:

```
Query OK, 1 row affected (0.00 sec)
```

You can run `SELECT * FROM books;` again to see the newly added row.

Modifying Data (UPDATE)

To change existing data in a table, use the `UPDATE` statement. Let's correct the spelling of "The Hobbbit".

```
UPDATE books
SET Title = "The Hobbit"
WHERE BookID = 7;
```

- `SET Title = "The Hobbit"` specifies the column to change and its new value.
- `WHERE BookID = 7` is crucial; it specifies *which row(s)* to update. Without a `WHERE` clause, `UPDATE` would change *all* rows in the table. **Output:**

```
Query OK, 1 row affected (0.00 sec)
Rows matched: 1  Changed: 1  Warnings: 0
```

Run `SELECT * FROM books WHERE BookID = 7;` to see the correction.

Using MariaDB involves understanding SQL syntax. It doesn't allow for typing mistakes or clauses in the wrong order, but with practice, it becomes straightforward.

Creating & Using Views Guide

This guide introduces SQL Views in MariaDB, virtual tables based on the result-set of a stored query. Learn how views simplify complex queries, enhance data security by restricting access, and provide an abstraction layer over your database tables through practical examples.

Prerequisites

- A basic understanding of SQL, particularly `JOIN` operations. (You may want to refer to More Advanced Joins.)
- Access to a MariaDB database.
- Privileges to `CREATE TABLE` and `CREATE VIEW`.

Setup: Example Employee Database

First, we'll create and populate two tables, `Employees` and `Hours`, to use in our examples. If you have already completed a tutorial using this database structure (e.g., from a "More Advanced Joins" guide), you might be able to skip this setup.

Employees Table:

```
CREATE TABLE `Employees` (
  `ID` TINYINT(3) UNSIGNED NOT NULL AUTO_INCREMENT,
  `First_Name` VARCHAR(25) NOT NULL,
  `Last_Name` VARCHAR(25) NOT NULL,
  `Position` VARCHAR(25) NOT NULL,
  `Home_Address` VARCHAR(50) NOT NULL,
  `Home_Phone` VARCHAR(12) NOT NULL,
  PRIMARY KEY (`ID`)
) ENGINE=MyISAM;

INSERT INTO `Employees` (`First_Name`, `Last_Name`, `Position`, `Home_Address`, `Home_Phone`)
VALUES
  ('Mustapha', 'Mond', 'Chief Executive Officer', '692 Promiscuous Plaza', '326-555-3492'),
  ('Henry', 'Foster', 'Store Manager', '314 Savage Circle', '326-555-3847'),
  ('Bernard', 'Marx', 'Cashier', '1240 Ambient Avenue', '326-555-8456'),
  ('Lenina', 'Crowne', 'Cashier', '281 Bumblepuppy Boulevard', '328-555-2349'),
  ('Fanny', 'Crowne', 'Restocker', '1023 Bokanovsky Lane', '326-555-6329'),
  ('Helmholtz', 'Watson', 'Janitor', '944 Soma Court', '329-555-2478');
```

Hours Table:

```
CREATE TABLE `Hours` (
  `ID` TINYINT(3) UNSIGNED NOT NULL,
  `Clock_In` DATETIME NOT NULL,
  `Clock_Out` DATETIME NOT NULL
) ENGINE=MyISAM;

INSERT INTO `Hours`
VALUES ('1', '2005-08-08 07:00:42', '2005-08-08 17:01:36'),
  ('1', '2005-08-09 07:01:34', '2005-08-09 17:10:11'),
  ('1', '2005-08-10 06:59:56', '2005-08-10 17:09:29'),
  ('1', '2005-08-11 07:00:17', '2005-08-11 17:00:47'),
  ('1', '2005-08-12 07:02:29', '2005-08-12 16:59:12'),
  ('2', '2005-08-08 07:00:25', '2005-08-08 17:03:13'),
  ('2', '2005-08-09 07:00:57', '2005-08-09 17:05:09'),
  ('2', '2005-08-10 06:58:43', '2005-08-10 16:58:24'),
  ('2', '2005-08-11 07:01:58', '2005-08-11 17:00:45'),
  ('2', '2005-08-12 07:02:12', '2005-08-12 16:58:57'),
  ('3', '2005-08-08 07:00:12', '2005-08-08 17:01:32'),
  ('3', '2005-08-09 07:01:10', '2005-08-09 17:00:26'),
  ('3', '2005-08-10 06:59:53', '2005-08-10 17:02:53'),
  ('3', '2005-08-11 07:01:15', '2005-08-11 17:04:23'),
  ('3', '2005-08-12 07:00:51', '2005-08-12 16:57:52'),
  ('4', '2005-08-08 06:54:37', '2005-08-08 17:01:23'),
  ('4', '2005-08-09 06:58:23', '2005-08-09 17:00:54'),
  ('4', '2005-08-10 06:59:14', '2005-08-10 17:00:12'),
  ('4', '2005-08-11 07:00:49', '2005-08-11 17:00:34'),
  ('4', '2005-08-12 07:01:09', '2005-08-12 16:58:29'),
  ('5', '2005-08-08 07:00:04', '2005-08-08 17:01:43'),
  ('5', '2005-08-09 07:02:12', '2005-08-09 17:02:13'),
  ('5', '2005-08-10 06:59:39', '2005-08-10 17:03:37'),
  ('5', '2005-08-11 07:01:26', '2005-08-11 17:00:03'),
  ('5', '2005-08-12 07:02:15', '2005-08-12 16:59:02'),
  ('6', '2005-08-08 07:00:12', '2005-08-08 17:01:02'),
  ('6', '2005-08-09 07:03:44', '2005-08-09 17:00:00'),
  ('6', '2005-08-10 06:54:19', '2005-08-10 17:03:31'),
  ('6', '2005-08-11 07:00:05', '2005-08-11 17:02:57'),
  ('6', '2005-08-12 07:02:07', '2005-08-12 16:58:23');
```

Building a Complex Query (Example: Employee Tardiness)

Let's say Human Resources needs a report on employees who are late (clock in after 7:00:59 AM) and do not make up the time at the end of their shift (work less than 10 hours and 1 minute).

Initial Query (Helmholtz's Lateness):

This query finds instances where Helmholtz was late within a specific week:

```
SELECT
  `Employees`.`First_Name`,
  `Employees`.`Last_Name`,
  `Hours`.`Clock_In`,
  `Hours`.`Clock_Out`
FROM `Employees`
INNER JOIN `Hours` ON `Employees`.`ID` = `Hours`.`ID`
WHERE `Employees`.`First_Name` = 'Helmholtz'
AND DATE_FORMAT(`Hours`.`Clock_In`, '%Y-%m-%d') >= '2005-08-08'
AND DATE_FORMAT(`Hours`.`Clock_In`, '%Y-%m-%d') <= '2005-08-12'
AND DATE_FORMAT(`Hours`.`Clock_In`, '%H:%i:%S') > '07:00:59';
```

Output:

```
+------------+-----------+---------------------+---------------------+
| First_Name | Last_Name | Clock_In            | Clock_Out           |
+------------+-----------+---------------------+---------------------+
| Helmholtz  | Watson    | 2005-08-09 07:03:44 | 2005-08-09 17:00:00 |
| Helmholtz  | Watson    | 2005-08-12 07:02:07 | 2005-08-12 16:58:23 |
+------------+-----------+---------------------+---------------------+
```

Refined Query (Policy Violators):

This query identifies all employees who were late and whose shift duration was less than 10 hours and 1 minute (601 minutes).

```
SELECT
  `Employees`.`First_Name`,
  `Employees`.`Last_Name`,
  `Hours`.`Clock_In`,
  `Hours`.`Clock_Out`,
  (601 - TIMESTAMPDIFF(MINUTE, `Hours`.`Clock_In`, `Hours`.`Clock_Out`)) AS Difference -- Corrected
Difference Calculation
FROM `Employees`
INNER JOIN `Hours` USING (`ID`) -- Simplified JOIN condition
WHERE DATE_FORMAT(`Hours`.`Clock_In`, '%Y-%m-%d') BETWEEN '2005-08-08' AND '2005-08-12'
  AND TIME(`Hours`.`Clock_In`) > '07:00:59'
  AND TIMESTAMPDIFF(MINUTE, `Hours`.`Clock_In`, `Hours`.`Clock_Out`) < 601;
```

Output of Refined Query (example structure):

```
+------------+-----------+---------------------+---------------------+------------+
| First_Name | Last_Name | Clock_In            | Clock_Out           | Difference |
+------------+-----------+---------------------+---------------------+------------+
| Mustapha   | Mond      | 2005-08-12 07:02:29 | 2005-08-12 16:59:12 |          4 |
... (other rows matching the criteria)
+------------+-----------+---------------------+---------------------+------------+
```

Creating and Using a View

The refined query is becoming complex. Storing this query logic in application code makes it harder to manage and means changes to table structures require application code changes. Views can simplify this.

A view is a virtual table based on the result-set of a stored query.

Creating the Employee_Tardiness View:

We use the refined query to create a view. SQL SECURITY INVOKER means the view runs with the permissions of the user querying it.

```
CREATE SQL SECURITY INVOKER VIEW Employee_Tardiness AS
SELECT
  `Employees`.`First_Name`,
  `Employees`.`Last_Name`,
  `Hours`.`Clock_In`,
  `Hours`.`Clock_Out`,
  (601 - TIMESTAMPDIFF(MINUTE, `Hours`.`Clock_In`, `Hours`.`Clock_Out`)) AS Difference
FROM `Employees`
INNER JOIN `Hours` USING (`ID`)
WHERE DATE_FORMAT(`Hours`.`Clock_In`, '%Y-%m-%d') BETWEEN '2005-08-08' AND '2005-08-12'
  AND TIME(`Hours`.`Clock_In`) > '07:00:59'
  AND TIMESTAMPDIFF(MINUTE, `Hours`.`Clock_In`, `Hours`.`Clock_Out`) < 601;
```

Querying the View:

Now, retrieving the tardiness data is much simpler:

```
SELECT * FROM Employee_Tardiness;
```

This will produce the same results as the complex “Refined Query” above.

You can also apply further conditions when querying the view:

```
SELECT * FROM Employee_Tardiness WHERE Difference >= 5;
```

Output (example structure, showing those at least 5 minutes short):

```
+------------+-----------+---------------------+---------------------+------------+
| First_Name | Last_Name | Clock_In            | Clock_Out           | Difference |
+------------+-----------+---------------------+---------------------+------------+
| Mustapha   | Mond      | 2005-08-12 07:02:29 | 2005-08-12 16:59:12 |          5 |
... (other rows where Difference >= 5)
+------------+-----------+---------------------+---------------------+------------+
```

Other Benefits and Uses of Views

- **Simplifying Complex Queries:** As demonstrated, views hide complex joins and calculations.
- **Restricting Data Access (Column-Level Security):** Views can expose only a subset of columns from underlying tables, preventing users or applications from seeing sensitive information (e.g., `Home_Address`, `Home_Phone` were not included in our `Employee_Tardiness` view).
- **Implementing Row-Level Security:** A view can include a `WHERE` clause that filters rows based on the user querying it or other criteria, effectively providing row-level access control. For updatable views, defining them with `WITH CHECK OPTION` (or the similar effect of a `CASCADE` clause mentioned in original text, usually `WITH CASCADED CHECK OPTION`) can ensure that `INSERT`s or `UPDATE`s through the view adhere to the view’s `WHERE` clause conditions.
- **Preemptive Optimization:** Complex, frequently used queries can be defined as views with optimal join strategies and indexing considerations. Other users or applications query the already optimized view, reducing the risk of running inefficient ad-hoc queries.
- **Abstracting Table Structures:** Views provide a consistent interface to applications even if the underlying table structures change (e.g., tables are normalized, split, or merged). The view definition can be updated to map to the new structure, while applications continue to query the unchanged view.

Summary of View Advantages

Views offer a powerful way to:

- **Simplify data access:** Make complex queries easier to write and understand.
- **Abstract database logic:** Separate application code from the complexities of the database schema.

- **Enhance security:** Control access to specific rows and columns.
- **Improve maintainability:** Changes to underlying tables can often be managed by updating the view definition without altering application queries.

Database Applications

> By Anders Karlsson, Principal Sales Engineer at MariaDB Plc — 24 minutes read

This document offers guidance on creating and maintaining database applications with minimal downtime and effort, covering aspects from database schema design to application code.

Here's a summary of key areas and advice covered; find the full guide on the subsequent pages.

- Database Design: A well-designed database is crucial. Standardization in naming conventions (e.g., `orders_t`), data types, character sets (preferably UTF-8 for full Unicode support, `utf8mb4`), and collations is highly recommended to ensure ease of maintenance.
- Data Types:
  - Choosing appropriate types: Consider if a number will be computed; if not, a string might be better (e.g., `VARCHAR` for product codes with leading zeros).
  - Text/String: Use `VARCHAR` and be generous with sizing, as schema upgrades for length extensions are undesirable. UTF-8 (specifically `utf8mb4`) is generally preferred for character sets, and consistency in collations simplifies maintenance.
  - Numeric: Use `BIGINT` for auto-generated primary keys to prevent overflow issues. Avoid `FLOAT` and `DOUBLE` for monetary values due to rounding issues; `DECIMAL` is more accurate.
  - Temporal: Understand the differences between `DATETIME` (stores time as is) and `TIMESTAMP` (affected by client-side time zones) before using them.
  - Other: Be cautious with `ENUM` and `SET` types, as adding values requires schema alteration.
- Schema Objects:
  - Views: Excellent for hiding complexity and supporting different schema versions. Naming views with version strings (`orders_v_1`) can be beneficial. They can also be used to reference data in newer schemas during migration.
- Application Code:
  - Separation of Concerns: While complete separation of application logic and database logic is difficult, practices like using ORMs and stored procedures can help.
  - Object Relational Mappers (ORM): Tools like Hibernate allow applications to be less reliant on specific database schema details, aiding maintenance, though performance and complex operations might still require attention.
  - Stored Procedures and Functions: Isolate database logic from application logic, making maintenance easier by centralizing complex SQL operations in the database layer.
  - Best Practices in Application SQL:
    - Avoid `SELECT *`: Explicitly list columns to prevent issues if table schema changes (column order or addition).
    - Avoid `INSERT` without column names: Always specify column names in `INSERT` statements to avoid errors when table schema changes.

    - Processing of column data: Be consistent; processing in the application can sometimes make SQL more readable.
    - Use of reserved words: Avoid using SQL reserved words for schema objects and column names, even if quoting them makes them valid.
    - Relying on non-explicit assumptions: Never assume row ordering without an `ORDER BY` clause. The order of returned rows is otherwise undetermined. Be cautious with `LIMIT` in `UPDATE` or `DELETE` without `ORDER BY`.
- Code and Schema Standardization: Adhering to internal standards for data types, column names, and database interaction improves maintainability and code readability.
- Complex SQL: Break down very complex SQL (especially `SELECT JOIN`s) into multiple statements or use temporary tables to improve readability and maintainability.
- Canary Testing:
    - Database Naming: Utilize the MariaDB `database` concept (similar to schema) as a namespace to allow different schemas to coexist, avoiding hard-coding database names.
    - Views: Create separate databases for new versions with views referencing data in older or newer schemas to manage transitions.
    - Replication: Use MariaDB replication, particularly statement-based replication (SBR), for canary testing by replicating from the production system to a new server with the updated schema.
    - Invisible Columns: A MariaDB feature allowing columns to exist without being exposed by default, useful in scenarios where old applications use `SELECT *` or `INSERT` without column names, allowing new columns to be added without breaking existing code.

Introduction & Background

Introduction

When designing database-based applications, one aspect that might always be considered at first is how you are supposed to maintain these applications; here, we mean maintenance in the sense of application code and database schemas being upgraded and how this can be done with minimum downtime and effort.

This document aims to look at some important aspects of this, from database schema design to application code. Most of these are not strict rules, but rather aspects to consider when working with applications. The document does not cover general application code aspects, only the aspects that deal with the database part of applications.

Background to Relational Database Applications

Relational database systems, more or less all of them using the SQL query language, have been around since the early 1980s, and things have changed a lot over that time. One aspect that applications using relational databases introduced was the separation of the application, dealing with logic, presentation, user interaction and similar aspects on one hand and the database structure and design on the other.

With relational databases came the relational database modelling and eventually the different normal forms of database design. Much of this has relaxed these days, but there are still things to consider here.

The introduction of logic in the database layer, such as stored procedures, triggers and other aspects, is somewhat blurring the line between code and data, but the general rules still hold.

This page is licensed: CC BY-SA / Gnu FDL

Database Design

Overview

The design of the database is a key here; a well-designed database with appropriate relationships, naming, etc., is still a solid foundation to build a structure on, but as things evolve, it will change with the application. The task is to implement necessary changes, but also to consider future enhancements in the design of the database.

Standardization

To make a database schema easy to maintain, it is best to adhere to some kind of naming standard. What this standard is has less importance than ensuring that it is adhered to. Some like to prefix a name with the type indicator, some like to suffix it, and others ignore this; whichever is your preference, stick to it.

```
CREATE TABLE `orders_t`(`order_id` BIGINT NOT NULL PRIMARY KEY,
   `order_date` DATETIME NOT NULL,
   `customer_id` BIGINT NOT NULL,
   FOREIGN KEY(`customer_id`) REFERENCES `customer_t`(`customer_id`));
```

In addition, sticking to a standard for data types to use, including character sets and collations, is a good practice.

Database Data Types

The data types used really need careful consideration. There are performance aspects here, but in addition, the ease of upgrading the schema should also be considered. Any data type has limitations in and of themselves, and in many cases, limits are introduced as part of a column definition, such as the maximum length of string types and the precision of numeric datatypes.

Choosing an Appropriate Data Type

In some cases, a suitable data type is obvious; in other cases, this is not the case. Take, for example, a product code consisting of 8 digits; is it best stored as an `INTEGER` or as a `VARCHAR(8)`? The former will be more compact in storage and will be faster, the latter less so. Also, are leading zeros significant? If this is the case, then an `INTEGER` is likely not a good option. Actually, in general, if you are not computing a number, it is likely better to be stored as a string.

Text / String Data Types

The most common text data types are variable length, so in general, there is no need to be conservative when sizing a `VARCHAR`, for example. In MariaDB, there is a limit on the total row size of a table, and in this calculation, the maximum size of `VARCHAR` is used, so this might be a reason not to extend this too much. In some cases, you know the maximum length of a `VARCHAR` column, and in that case, it should be used, of course, but be careful, as things might change over time, say some code of some kind might be extended in the future.

In other situations, you cannot really tell what the maximum might be, say a name, then make sure that there is ample space available, having to upgrade a schema just because you have to extend the size of a `VARCHAR` column is unnecessary.

Character Sets and Collations

One issue that needs to be considered is what character set to use for text strings. In most cases, it is recommended that UTF-8 be used, but note that MariaDB has a few options here; either you can use 3-byte UTF-8, called utf8mb3, which allows for 2-byte Unicode or 4-byte, called utf8mb4, which allows full Unicode support. When you use UTF-8, though, remember that storage of strings might be longer. MariaDB ensures that space is allocated as appropriate, but the max potential length of a `VARCHAR(8)` string using utf8mb3 will be 24 bytes, and when it comes to calculating the maximum row size, this is calculated as 24, not 8, bytes.

Collations determine how a string is sorted, for example, when an `ORDER BY` is used and when indexes are created. You really do want to avoid upgrading a schema to change the collation of a column in a table, so be careful here.

Best Practices With Regard to String Data Types

It is recommended that you allow as much space as possible when you don't know the maximum length of a column in a table. It is recommended to use UTF-8 for string data; it does have some drawbacks, but in the end, it is the best general-use character set. It might be useful to use a single-byte character set in some cases, say when using some alphanumeric code item such as a product code, but mostly you are best off with UTF-8 even here, as mixing different data types makes things unnecessarily complicated.

Similar things can be said for collations; there are few reasons to deviate from using just a single collation for a specific application database from the point of view of creating a schema that can be easily maintained at least. From a performance point of view, there are things to consider when determining which collation to use.

Numeric Data Types

Numeric data types come in several flavors, from a high level we are looking at integer types, floating point types and fixed-point types. In MariaDB, all numeric types are fixed-size storage. From the point of view of schema maintenance, the first thing to look for when it comes to creating a database schema that will need less maintenance is to ensure that values fit in the types used. `BIGINT` instead of `INTEGER` is often a good idea, in particular when used for auto-generated primary keys.

Another thing to watch out for is `FLOAT` and `DOUBLE`, including aliases for these, as they are floating-point, which means there might be rounding issues. Using these types for monetary values might not always be a good idea.

An alternative to `FLOAT` and `DOUBLE` is to use the fixed-point `DECIMAL` type, which is exact. Note also that in `SQL_MODE=Oracle` in MariaDB, the Oracle type `NUMERIC` is an alias for `DECIMAL`.

Temporal Data Types

MariaDB has a range of temporal types, from the standard `DATETIME` and `TIMESTAMP` to the more specialised `DATE`, `YEAR` and `TIME`. The by far most used ones are `DATETIME` and `TIMESTAMP`, and there are some things to consider when it comes to maintenance. `DATETIME` and `TIMESTAMP` both store similar values, but there is a difference in that `DATETIME` stores the time as it is, whereas `TIMESTAMP` takes the time zone on the client side into effect.

From a schema maintenance point of view, make sure that you understand how these two types work before using them.

Other Data Types

Most database systems on the market have types that are specific to that system in particular, in MariaDB, which includes `ENUM` and `SET` types. Some types are little used, like BIT and smaller variations of `INTEGER` types. As for `ENUM` and `SET`, these have some useful attributes in that they, on the one hand, require limited storage, but to extend them with additional values, the schema has to be altered, which might be an issue in many cases.

Schema Objects

Beyond this, there are other objects to handle when it comes to schema and application maintenance. Here, we will look at some of them from the point of view of creating a schema that allows itself to be maintained with limited effort.

Views

Using views has several advantages, and although using views might have performance issues, they provide many advantages when it comes to maintaining a database schema. When considering that, this assumes that the views are created with performance and maintenance in mind.

Very complex queries that might need to be maintained can well be put in views. It may also be advantageous to use views to support different versions of a schema over time; adding a version string to VIEW names might well be a good idea.

```
CREATE VIEW orders_v_1
AS
SELECT o.`order_id`, o.`order_date` FROM `orders_t` o;
```

Application Code

Although relational database applications strive to separate application code from database data, this is only possible to a limited extent. That said, there are means to work with database and application design that make maintaining database schema and applications easier. The task at hand then, on the application side of things, is to make the application easy to maintain and as flexible as possible when it comes to integrating with the database on one hand, and on the other hand ensure that the measures taken don't take a toll on features, functionality or performance.

Object Relational Mappers (ORM)

Using an ORM, such as Hibernate for Java applications, makes it possible to build applications that do not rely on the lowest detail of the database schema. On the other hand, performance is sometimes an issue and, in some cases, complex relational operations might still need to be hard-coded. Despite this, hibernate is often a good way to create applications and database schemas that are easy to maintain.

Stored Procedures and Functions

Using database stored procedures is another way of isolating database logic from application logic. One advantage here is that if applications call stored procedures instead of issuing SQL statements, then we can keep a clear differentiator between the database and backend processing and application-level processing. A disadvantage is that the connection between the backend logic and the structure of the data is still there, it is just somewhere else than in the application, but this still makes maintenance easier in many ways.

It is also common not to drive this too far, i.e. complex SQL and code that truly belongs in the backend can be in the database, whereas more basic SQL and simple SELECTs can be kept as they are in the application.

Views

Views are useful to separate complex processing, such as advanced JOIN operations, from the application. In some cases, VIEWs introduce performance issues, but these cases are rare.

Application Code

As for database code / SQL in applications, there are several best practices to stick to.

SELECT *

Avoid `SELECT *` in applications; these have several bad effects, such as assuming in the application what columns are in a table, no more and no less, and in what order. This is not a good idea. In addition, selecting more columns than necessary does affect performance and may cause the optimizer to use a non-optimal path. Note that `SELECT *` makes two assumptions: first that it assumes which columns exist in a table, and secondly, the order in which these columns are defined. Getting any of these wrong can break things unnecessarily, and using this construct in application code makes schema changes more difficult.

INSERT Without Column Names

Just as in the case of `SELECT *`, an `INSERT` without column names, such as this …

```
INSERT INTO `orders_t` VALUES(1, '2025-06-01 12:00:00');
```

… is a bad idea. The proper way to write an SQL statement like this is:

```
INSERT INTO `orders_t`(`order_id`, `order_date`)
  VALUES(1, '2025-06-01 12:00:00');
```

Not doing this may cause errors in the application if the table is changed, such as when columns are added or the order of the columns is changed.

Processing of Column Data

When data is returned from a `SELECT` statement, it is sometimes tempting to put processing of values in the SQL statement, like this:

```
SELECT YEAR(`order_date`) AS `order_year` FROM `orders_t`;
```

This is not incorrect in any way and is perfectly valid, but sometimes it is better to do this processing in the application. The best is to be consistent and the issue with this kind of construct is that it sometimes makes the SQL less readable than necessary.

Use of Reserved Words in the Schema

It is possible to use reserved words in names of schema objects and in the SQL itself, as here:

```
CREATE TABLE `order`(`order_id` INTEGER NOT NULL PRIMARY KEY);
```

And here:

```
SELECT order_id AS `order` FROM orders_t;
```

Both of these are valid constructs, but are not really recommended. The keyword order used above is likely among the most likely reserved words to use in a schema, but there are more. It is best to avoid them completely, even though quoting them makes the schema and SQL syntax valid.

Relying on Nonexplicit Assumptions

This is an issue that sometimes comes into play, where an application assumes data is processed in a particular order or in a particular way. This really should never be done in an application. One of the best examples is the ordering of rows retrieved; one should not even rely on data being returned in the order of a `PRIMARY KEY` or some index. Example:

```
MariaDB> SELECT `order_date` FROM `orders_t`;
+---------------------+
| order_date          |
+---------------------+
| 2024-05-17 18:01:01 |
| 2025-12-12 18:44:08 |
| 2025-12-12 18:44:17 |
| 2025-09-09 14:57:47 |
+---------------------+
4 rows in set (0.000 sec)

MariaDB> ALTER TABLE `orders_t` ADD KEY(`order_date`);
Query OK, 0 rows affected (0.034 sec)
Records: 0  Duplicates: 0  Warnings: 0

MariaDB> SELECT `order_date` FROM `orders_t`;
+---------------------+
| order_date          |
+---------------------+
| 2024-05-17 18:01:01 |
| 2025-09-09 14:57:47 |
| 2025-12-12 18:44:08 |
| 2025-12-12 18:44:17 |
+---------------------+
4 rows in set (0.003 sec)
```

In the example, the order of the rows returned changed after the index was created, as the index can be used to fetch the data, and when the optimizer does that, it processes the index in order, which means the data is returned in the order of the index. Relying on this ordering in the application is not a good idea, though. If you require data to be returned in a particular order, then you have to use an `ORDER BY` clause; if you don't, the row ordering should be treated as being undetermined.

Another example is the `LIMIT` clause. When using `LIMIT` with a `SELECT`, the rows that are returned are undetermined unless an `ORDER BY` clause is provided. When using a `LIMIT` clause with an `UPDATE` or `DELETE` statement, it is even more important to understand that ordering is not fixed unless an `ORDER BY` statement is used. In general, I'd be careful with using the `LIMIT` clause for `UPDATE` and `DELETE` unless there is a good reason to do so.

There are other assumptions than row ordering, but it is one of the most common issues.

Code and Schema Standardization

Following some internal standards is really helpful when it comes to building applications that can be maintained. Standardizing how to determine the data type, the column name and how to interact with the database schema is a good first step in making an application easy to maintain over time. This also helps in making application code easy to read, which is also helpful.

Complex SQL

There are situations where the application-level SQL gets really complex, sometimes too complex, which in turn makes the code hard to maintain. In those cases, it is sometimes useful to break up a very complex SQL `SELECT` into multiple statements. In particular, complex `SELECT JOIN` queries are troublesome in this respect. If a `JOIN` is not a straight equi-join but a more complex one, for example, joining of a part of a database column, say the `YEAR` part of a `DATETIME` field, then things get really complex. An alternative is sometimes to use temporary tables, which are very efficient in MariaDB, instead of a single very complex `SELECT`.

Canary Testing

For canary testing new versions of an application, there are some tools to work with, but it has to be said that this is hardly ever 100% clear. If we assume that the advice above has been followed to some extent, then the following are some tools to work with.

Database Naming

In a MariaDB instance, there is the concept of a database, which is similar to a schema. A database is a kind of namespace, which means that an object, say a table, in one database may have the same name as an object in some other database in the same instance. Given this, databases are a key to allowing somewhat different schemas to coexist, which in turn means that it is good practice not to hard-code the database name in applications or schema objects, unless this makes sense.

Views

Views are an excellent way of hiding complexities, and a good way of dealing with this is to have a separate database for a new version with `VIEW`s referencing the actual data in some other database.

```
MariaDB> USE prod_v2;
MariaDB> CREATE VIEW `orders_t` AS
  SELECT `order_id`, `order_date` FROM `prod_v1`.`orders_t`;
```

When adding a new version of the schema/application, it is sometimes necessary to migrate the data to the new schema and have a `VIEW` in the “old” schema referencing the new one. A view is not always necessary in this case, but any added columns have to be handled by a trigger or by a sensible default.

```
MariaDB> USE prod_v2;
MariaDB> CREATE TABLE `orders_t`(
  `order_id` INTEGER NOT NULL PRIMARY KEY,
  `order_date` DATETIME NOT NULL,
  `customer_id` INTEGER NOT NULL DEFAULT 0);
MariaDB> INSERT INTO `orders_t` SELECT `order_id`, `order_date`
  FROM `prod_v1`.`orders_t`;

MariaDB> USE prod_v1;
MariaDB> RENAME TABLE `orders_t` TO `orders_t_v1`;
MariaDB> CREATE VIEW `orders_t` AS
  SELECT `order_id`, `order_date` FROM `prod_v2`.`orders_t`;
```

Replication

A good way of dealing with canary testing with MariaDB is to use replication, which works even in cases with schemas that are different, to an extent, if statement-based replication (SBR) is used. Using this, a new version is built on one server and a new schema is installed there. This is then set to replicate from the current production system. This is not likely to work for all cases, but in many cases, this is a useful tool to allow for canary testing.

Invisible Columns

Hidden or invisible columns in MariaDB are a feature that allows a column to exist in a table without being exposed by default, for instance a `SELECT *` or an `INSERT` without column names will not touch this column. If the advice given in the previous sections of the document is followed, then this should not be necessary much, but in some cases, it is still a useful feature.

For example, in the example above with the orders_t table, if it is the case that the current application actually does `INSERT` without specifying the columns to insert into, then a new column, say customer_id, cannot be added. We can then use an invisible column to support this application, including a new version that does use column names in the `INSERT` and also use the customer_id column:

```
MariaDB> USE prod_v1

MariaDB> ALTER TABLE `orders_t`
  ADD `customer_id` INTEGER NOT NULL DEFAULT 0 INVISIBLE;
MariaDB> SELECT * FROM `orders_t`;
+----------+---------------------+
| order_id | order_date          |
+----------+---------------------+
|        1 | 2024-05-17 18:01:01 |
|        2 | 2025-12-12 18:44:08 |
+----------+---------------------+
2 rows in set (0.004 sec)

MariaDB> INSERT INTO `orders_t`
  (`order_id`, `order_date`, `customer_id`) VALUES(3, NOW(), 2);
```

Basic Queries

Connecting to MariaDB

MariaDB is a database system, a database server. To interface with the MariaDB server, you can use a client program, or you can write a program or script with one of the popular programming languages (e.g., PHP) using an API (Application Programming Interface) to interface with the MariaDB server. For the purposes of this article, we will focus on using the default client that comes with MariaDB called `mariadb`. With this client, you can either enter queries from the command-line, or you can switch to a terminal, that is to say, monitor mode. To start, we'll use the latter.

From the Linux command-line, you would enter the following to log in as the root user and to enter monitor mode:

```
mariadb -u root -p -h localhost
```

The `-u` option is for specifying the user name. You would replace `root` here if you want to use a different user name. This is the MariaDB user name, not the Linux user name. The password for the MariaDB user `root` will probably be different from the Linux user `root`. Incidentally, it's not a good security practice to use the `root` user unless you have a specific administrative task to perform for which only `root` has the needed privileges.

The `-p` option above instructs the `mariadb` client to prompt you for the password. If the password for the `root` user hasn't been set yet, then the password is blank and you would just hit [Enter] when prompted. The `-h` option is for specifying the host name or the IP address of the server. This would be necessary if the client is running on a different machine than the server. If you've secure-shelled into the server machine, you probably won't need to use the host option. In fact, if you're logged into Linux as `root`, you won't need the user option—the `-p` is all you'll need. Once you've entered the line above along with the password when prompted, you are logged into MariaDB through the client. To exit, type quit or exit and press [Enter].

Creating a Structure

In order to be able to add and to manipulate data, you first have to create a database structure. Creating a database is simple. You would enter something like the following from within the mariadb client:

```
CREATE DATABASE bookstore;

USE bookstore;
```

This very minimal, first SQL statement will create a sub-directory called bookstore on the Linux filesystem in the directory which holds your MariaDB data files. It won't create any data, obviously. It'll just set up a place to add tables, which will in turn hold data. The second SQL statement above will set this new database as the default database. It will remain your default until you change it to a different one or until you log out of MariaDB.

The next step is to begin creating tables. This is only a little more complicated. To create a simple table that will hold basic data on books, we could enter something like the following:

```
CREATE TABLE books (
isbn CHAR(20) PRIMARY KEY,
title VARCHAR(50),
author_id INT,
publisher_id INT,
year_pub CHAR(4),
description TEXT );
```

This SQL statement creates the table books with six fields, or rather columns. The first column (isbn) is an identification number for each row—this name relates to the unique identifier used in the book publishing business. It has a fixed-width character type of 20 characters. It are the primary key column on which data are indexed. The column data type for the book title is a variable width character column of fifty characters at most. The third and fourth columns are used for identification numbers for the author and the publisher. They are integer data types. The fifth column is used for the publication year of each book. The last column is for entering a description of each book. It's a TEXT data type, which means that it's a variable width column and it can hold up to 65535 bytes of data for each row. There are several other data types that may be used for columns, but this gives you a good sampling.

To see how the table we created looks, enter the following SQL statement:

```
DESCRIBE books;
+-------------+-------------+------+-----+---------+-------+
| Field       | Type        | Null | Key | Default | Extra |
+-------------+-------------+------+-----+---------+-------+
| isbn        | char(20)    | NO   | PRI | NULL    |       |
| title       | varchar(50) | YES  |     | NULL    |       |
| author_id   | int(11)     | YES  |     | NULL    |       |
| publisher_id | int(11)    | YES  |     | NULL    |       |
| year_pub    | char(4)     | YES  |     | NULL    |       |
| description | text        | YES  |     | NULL    |       |
+-------------+-------------+------+-----+---------+-------+
```

To change the settings of a table, you can use the ALTER TABLE statement. I'll cover that statement in another article. To delete a table completely (including its data), you can use the DROP TABLE statement, followed by the table name. Be careful with this statement since it's not reversible.

The next table we'll create for our examples is the authors table to hold author information. This table will save us from having to enter the author's name and other related data for each book written by each author. It also helps to ensure consistency of data: there's less chance of inadvertent spelling deviations.

```
CREATE TABLE authors
(author_id INT AUTO_INCREMENT PRIMARY KEY,
name_last VARCHAR(50),
name_first VARCHAR(50),
country VARCHAR(50) );
```

We'll join this table to the books table as needed. For instance, we would use it when we want a list of books along with their corresponding authors' names. For a real bookstore's database, both of these tables would probably have more columns. There would also be several more tables. For the examples that follow, these two tables as they are enough.

Minor Items

Before moving on to the next step of adding data to the tables, let me point out a few minor items that I've omitted mentioning. SQL statements end with a semi-colon (or a \G). You can spread an SQL statement over multiple lines. However, it won't be passed to the server by the client until you terminate it with a semi-colon and hit [Enter]. To cancel an SQL statement once you've started typing it, enter `\c` and press [Enter].

As a basic convention, reserved words are printed in all capital letters. This isn't necessary, though. MariaDB is case-insensitive with regards to reserved words. Database and table names, however, are case-sensitive on Linux. This is because they reference the related directories and files on the filesystem. Column names aren't case sensitive since they're not affected by the filesystem, per se. As another convention, we use lower-case letters for structural names (e.g., table names). It's a matter of preference for deciding on names.

Entering Data

The primary method for entering data into a table is to use the INSERT statement. As an example, let's enter some information about an author into the authors table. We'll do that like so:

```
INSERT INTO authors
(name_last, name_first, country)
VALUES('Kafka', 'Franz', 'Czech Republic');
```

This will add the name and country of the author Franz Kafka to the authors table. We don't need to give a value for the author_id since that column was created with the AUTO_INCREMENT option. MariaDB will automatically assign an identification number. You can manually assign one, especially if you want to start the count at a higher number than 1 (e.g., 1000). Since we are not providing data for all of the columns in the table, we have to list the columns for which we are giving data and in the order that the data is given in the set following the VALUES keyword. This means that we could give the data in a different order.

For an actual database, we would probably enter data for many authors. We'll assume that we've done that and move on to entering data for some books. Below is an entry for one of Kafka's books:

```
INSERT INTO books
(title, author_id, isbn, year_pub)
VALUES('The Castle', '1', '0805211063', '1998');
```

This adds a record for Kafka's book, *The Castle*. Notice that we mixed up the order of the columns, but it still works because both sets agree. We indicate that the author is Kafka by giving a value of 1 for the author_id. This is the value that was assigned by MariaDB when we entered the row for Kafka earlier. Let's enter a few more books for Kafka, but by a different method:

```
INSERT INTO books
(title, author_id, isbn, year_pub)
VALUES('The Trial', '1', '0805210407', '1995'),
('The Metamorphosis', '1', '0553213695', '1995'),
('America', '1', '0805210644', '1995');
```

In this example, we've added three books in one statement. This allows us to give the list of column names once. We also give the keyword `VALUES` only once, followed by a separate set of values for each book, each contained in parentheses and separated by commas. This cuts down on typing and speeds up the process. Either method is fine and both have their advantages. To be able to continue with our examples, let's assume that data on thousands of books has been entered. With that behind us, let's look at how to retrieve data from tables.

Retrieving Data

The primary method of retrieving data from tables is to use a SELECT statement. There are many options available with the SELECT statement, but you can start simply. As an example, let's retrieve a list of book titles from the books table:

```
SELECT title
FROM books;
```

This will display all of the rows of books in the table. If the table has thousands of rows, MariaDB will display thousands. To limit the number of rows retrieved, we could add a LIMIT clause to the SELECT statement like so:

```
SELECT title
FROM books
LIMIT 5;
```

This will limit the number of rows displayed to five. To be able to list the author's name for each book along with the title, you will have to join the books table with the authors table. To do this, we can use the JOIN clause like so:

```
SELECT title, name_last
FROM books
JOIN authors USING (author_id);
```

Notice that the primary table from which we're drawing data is given in the `FROM` clause. The table to which we're joining is given in the JOIN clause along with the commonly named column (i.e., author_id) that we're using for the join.

To retrieve the titles of only books written by Kafka based on his name (not the author_id), we would use the `WHERE` clause with the SELECT statement. This would be entered like the following:

```
SELECT title AS 'Kafka Books'
FROM books
JOIN authors USING (author_id)
WHERE name_last = 'Kafka';

+------------------+
| Kafka Books      |
+------------------+
| The Castle       |
| The Trial        |
| The Metamorphosis |
| America          |
+------------------+
```

This statement will list the titles of Kafka books stored in the database. Notice that I've added the `AS` parameter next to the column name title to change the column heading in the results set to Kafka Books. This is known as an alias. Looking at the results here, we can see that the title for one of Kafka's books is incorrect. His book Amerika is spelled above with a "c" in the table instead of a "k". This leads to the next section on changing data.

Changing & Deleting Data

In order to change existing data, a common method is to use the UPDATE statement. When changing data, though, we need to be sure that we change the correct rows. In our example, there could be another book with the title *America* written by a different author. Since the key column isbn has only unique numbers and we know the ISBN number for the book that we want to change, we can use it to specify the row.

```
UPDATE books
SET title = 'Amerika'
WHERE isbn = '0805210644';
```

This will change the value of the title column for the row specified. We could change the value of other columns for the same row by giving the column = value for each, separated by commas.

If we want to delete a row of data, we can use the DELETE statement. For instance, suppose that our fictitious bookstore has decided no longer to carry books by John Grisham. By first running a SELECT statement, we determine the identification number for the author to be 2034. Using this author identification number, we could enter the following:

```
DELETE FROM books
WHERE author_id = '2034';
```

This statement will delete all rows from the table books for the author_id given. To do a clean job of it, we'll have to do the same for the authors table. We would just replace the table name in the statement above; everything else would be the same.

Conclusion

This is a very basic primer for using MariaDB. Hopefully, it gives you the idea of how to get started with MariaDB. Each of the SQL statements mentioned here have several more options and clauses each. We will cover these statements and others in greater detail in other articles. For now, though, you can learn more about them from experimenting and by further reading of the documentation online documentation.

Backup and Restore Overview

This article briefly discusses the main ways to backup MariaDB. For detailed descriptions and syntax, see the individual pages. More detail is in the process of being added.

Logical vs Physical Backups

Logical backups consist of the SQL statements necessary to restore the data, such as CREATE DATABASE, CREATE TABLE and INSERT.

Physical backups are performed by copying the individual data files or directories.

The main differences are as follows:

- logical backups are more flexible, as the data can be restored on other hardware configurations, MariaDB versions or even on another DBMS, while physical backups cannot be imported on significantly different hardware, a different DBMS, or potentially even a different MariaDB version.
- logical backups can be performed at the level of database and table, while physical databases are the level of directories and files. In the MyISAM and InnoDB storage engines, each table has an equivalent set of files.
- logical backups are larger in size than the equivalent physical backup.
- logical backups takes more time to both backup and restore than the equivalent physical backup.
- log files and configuration files are not part of a logical backup

Backup Tools

`mariadb-backup`

The mariadb-backup program is a physical online backup tool and a fork of Percona XtraBackup with added support for compression and data-at-rest encryption.

Storage Engines and Backup Types

MariaDB Backup creates a file-level backup of data from the MariaDB Server data directory. This backup includes temporal data, and the encrypted and unencrypted tablespaces of supported storage engines (e.g., InnoDB, MyRocks, Aria).

MariaDB Server implements:

- Full backups, which contain all data in the database.
- Incremental backups, which contain modifications since the last backup.
- Partial backups, which contain a subset of the tables in the database.

Backup support is specific to storage engines. All supported storage engines enable full backup. The InnoDB storage engine additionally supports incremental backup.

Non-Blocking Backups

A feature of MariaDB Backup and MariaDB Server, non-blocking backups minimize workload impact during backups. When MariaDB Backup connects to MariaDB Server, staging operations are initiated to protect data during read.

Non-blocking backup functionality differs from historical backup functionality in the following ways:

- MariaDB Backup includes optimizations to backup staging, including DDL statement tracking, which reduces lock-time during backups.
- MariaDB Backup in MariaDB Community Server 10.4 and later will block writes, log tables, and statistics.
- Older releases used `FLUSH TABLES WITH READ LOCK`, which closed open tables and only allowed tables to be reopened with a read lock during the duration of backups.

Understanding Recovery

Full backups produced using MariaDB Server are not initially point-in-time consistent, and an attempt to restore from a raw full backup will cause InnoDB to crash to protect the data. Incremental backups contain only the changes since the last backup and cannot be used standalone to perform a restore.

To restore from a backup, you first need to prepare the backup for point-in-time consistency using the `--prepare` command:

- Running `--prepare` on a *full backup* synchronizes the tablespaces, ensuring they are point-in-time consistent.
- Running `--prepare` on an *incremental backup* synchronizes the tablespaces and applies the updated data into the previous full backup.
- Running `--prepare` on data used for a *partial restore* requires the `--export` option to create the necessary `.cfg` files.

Restore Requires Empty Data Directory

For MariaDB Backup to safely restore data from full and incremental backups, the data directory must be empty. When MariaDB Backup restores from a backup using `--copy-back` or `--move-back`, it copies or moves the backup files into the MariaDB Server data directory.

Creating the Backup User

When MariaDB Backup performs a backup operation, it connects to the running MariaDB Server to manage locks and backup staging that prevent the Server from writing to a file while being read. It is recommended that a dedicated user be created and authorized to perform backups:

```
CREATE USER 'mariabackup'@'localhost' IDENTIFIED BY 'mbu_passwd';
GRANT RELOAD, PROCESS, LOCK TABLES, BINLOG MONITOR
      ON * TO 'mariabackup'@'localhost';
```

> **Note:**
>
> While MariaDB Backup requires a user for backup operations, no user is required for restore operations since restores occur while MariaDB Server is not running.

`mariadb-dump`

mariadb-dump (previously mysqldump) performs a logical backup. It is the most flexible way to perform a backup and restore, and a good choice when the data size is relatively small.

For large datasets, the backup file can be large, and the restore time lengthy.

`mariadb-dump` dumps the data into SQL format (it can also dump into other formats, such as CSV or XML) which can then easily be imported into another database. The data can be imported into other versions of MariaDB, MySQL, or even another DBMS entirely, assuming there are no version or DBMS-specific statements in the dump.

mariadb-dump dumps triggers along with tables, as these are part of the table definition. However, stored procedures, views, and events are not, and need extra parameters to be recreated explicitly (for example, `--routines` and `--events`). Procedures and functions are however also part of the system tables (for example mysql.proc).

InnoDB Logical Backups

InnoDB uses the buffer pool, which stores data and indexes from its tables in memory. This buffer is very important for performance. If InnoDB data doesn't fit the memory, it is important that the buffer contains the most frequently accessed data. However, last accessed data is candidate for insertion into the buffer pool. If not properly configured,

when a table scan happens, InnoDB may copy the whole contents of a table into the buffer pool. The problem with logical backups is that they always imply full table scans.

An easy way to avoid this is by increasing the value of the innodb_old_blocks_time system variable. It represents the number of milliseconds that must pass before a recently accessed page can be put into the "new" sublist in the buffer pool. Data which is accessed only once should remain in the "old" sublist. This means that they will soon be evicted from the buffer pool. Since during the backup process the "old" sublist is likely to store data that is not useful, one could also consider resizing it by changing the value of the innodb_old_blocks_pct system variable.

It is also possible to explicitly dump the buffer pool on disk before starting a logical backup, and restore it after the process. This will undo any negative change to the buffer pool which happens during the backup. To dump the buffer pool, the innodb_buffer_pool_dump_now system variable can be set to `ON`. To restore it, the innodb_buffer_pool_load_now system variable can be set to `ON`.

`mariadb-dump` Examples

Backing up a single database

```
mariadb-dump db_name > backup-file.sql
```

Restoring or loading the database

```
mariadb db_name < backup-file.sql
```

See the mariadb-dump page for detailed syntax and examples.

`mariadb-hotcopy`

mariadb-hotcopy performs a physical backup, and works only for backing up MyISAM and ARCHIVE tables. It can only be run on the same machine as the location of the database directories.

`mariadb-hotcopy` Examples

```
mariadb-hotcopy db_name [/path/to/new_directory]
mariadb-hotcopy db_name_1 ... db_name_n /path/to/new_directory
```

Percona XtraBackup

Percona XtraBackup is **not supported** in MariaDB. mariadb-backup is the recommended backup method to use instead of Percona XtraBackup. See Percona XtraBackup Overview: Compatibility with MariaDB for more information.

Percona XtraBackup is a tool for performing fast, hot backups. It was designed specifically for XtraDB/InnoDB databases, but can be used with any storage engine (although not with encryption and compression). It is not included with MariaDB.

Filesystem Snapshots

Some filesystems, like Veritas, support snapshots. During the snapshot, the table must be locked. The proper steps to obtain a snapshot are:

- From the mariadb client, execute FLUSH TABLES WITH READ LOCK. The client must remain open.
- From a shell, execute `mount vxfs snapshot`
- The client can execute UNLOCK TABLES.
- Copy the snapshot files.
- From a shell, unmount the snapshot with `umount snapshot`.

LVM

Widely-used physical backup method, using a Perl script as a wrapper.

> **Warning:**
>
> **LVM snapshots are not a standalone DBMS backup solution.**
> LVM operates at the block level, meaning it is "database-blind." It captures a crash-consistent state, identical to a sudden power failure, ignoring data cached in RAM. Without flushing buffers and locking tables, snapshots risk torn pages and permanent corruption.
> Furthermore, the Copy-on-Write (CoW) mechanism significantly degrades production performance. Snapshots also exist on the same physical disks; they are not true backups and offer no protection against hardware failure. Always use application-aware tools (like mariadb-backup) to ensure data integrity.

dbForge Studio for MySQL

Besides the system utilities, it is possible to use third-party GUI tools to perform backup and restore operations. In this context, it is worth mentioning dbForge Studio for MySQL, a feature-rich database IDE that is fully compatible with MariaDB and delivers extensive backup functionality.

The backup and restore module of the Studio allows precise configuration and management of full and partial backups up to particular database objects. The feature of scheduling regular backups offers specific settings to handle errors and keep a log of them. Additionally, settings and configurations can be saved for later reuse.

These operations are wizard-aided allowing users to set up all tasks in a visual mode.

Forming a Backup Strategy

Overview

The strategy applied when implementing data backups depends on business needs.

Data backup strategy depends on business needs. Business needs can be evaluated by performing a data inventory, determining data recovery objectives, considering the replication environment, and considering encryption requirements. Also critical is a backup storage strategy and testing backup and recovery procedures.

Data Inventory

Backup strategy requirements flow from the understanding you build by performing a data inventory. A data inventory is established by asking questions such as:

1. What data is housed in the databases?
2. What business purpose does this data serve?
3. How long does the data needed to be retained in order to meet this business purpose?
4. Are there any legal or regulatory requirements, which would limit the length of data retention?

Recovery Objectives

Data recovery requirements are often defined in terms of Recovery Point Objective (RPO) and Recovery Time Objective (RTO). RTO and RPO are considered in the context of the data identified in the data inventory.

Recovery Point Objective (RPO) defines the maximum amount of data a business is willing to lose. For example, a business can define a RPO of 24 hours.

Recovery Time Objective (RTO) defines how quickly a business needs to restore service in the event of a fault. For example, a business can define a RTO of 8 hours.

Backup strategy plays a substantial role in achieving RPO and RTO.

Achieving RPO

RPO depends on completion of backups, which provide a viable recovery point. Since RPO is measured at backup completion, not backup initiation, backup jobs must be scheduled at an interval smaller than the RPO.

Techniques for achieving RPO include:

- Frequent incremental backups and less frequent full backups.
- Performing backups in conjunction with replication and clustering to eliminate impact on production workloads, allowing a higher backup frequency.
- Automated monitoring of backup status.
- Automated testing of backups.

Achieving RTO

The RTO window typically commences at the point when a decision is made by the business to recover from backups, not at the start of an incident.

Techniques for achieving RTO include:

- Leveraging information produced during incident response, which can reduce the set of data to restore from backups, or identify specific data validation requirements dependent on the nature of the incident.
- Having fast access to backup data. Performance requirements of backup infrastructure should be understood for both backup and restoration workloads.
- Using delayed replication, either within the same data center or to a different data center, can provide shorter path to recovery. This is particularly true when coupled with robust application monitoring, which allows intervention before the window of delay elapses.
- Applying written and tested recovery procedures, which designate the systems and commands to be used during recovery.
- Performing drills and exercises that periodically test recovery procedures to confirm readiness.

Replication Considerations

MariaDB Enterprise Server supports several implementations of replication, which accurately duplicates data from one Server to one or more other Servers. The use of a dedicated replica as a source for backups can minimize workload impact.

MariaDB Enterprise Cluster implements virtually synchronous replication, where each Server instance contains a replica of all of the data for the Cluster. Backups can be performed from any node in the Cluster.

Encryption Considerations

MariaDB Enterprise Server supports encryption on disk (data-at-rest encryption) and on the network (data-in-transit encryption).

MariaDB Enterprise Backup copies tablespaces from disk. When data-at-rest encryption is enabled, backups contain encrypted data.

MariaDB Enterprise Backup supports TLS encryption for communications with MariaDB Enterprise Server. To enable TLS encryption, set TLS options from the command-line or in the configuration file:

```
mariadb-backup --backup \
      --target-dir=/data/backups/full \
      --user=mariadb-backup \
      --password=mbu_passwd \
      --ssl-ca=/etc/my.cnf.d/certs/ca.pem \
      --ssl-cert=/etc/my.cnf.d/certs/client-cert.pem \
      --ssl-key=/etc/my.cnf.d/certs/client-key.pem
```

Backup Storage Considerations

How backups are stored can impact backup viability. Backup storage also presents separate risks. These risks need to be carefully considered:

- Backup data should always be stored separately from the system being backed up, and separate from the system used for recovery.
- Backup data should be subject to equal or more controls than data in production databases. For example, backup data should generally be encrypted even where a decision has bee made that a production database will not use data-at-rest encryption.
- Business requirements may define a need for offsite storage of backups as a means of guaranteeing delivery on RPO. In these cases you should also consider onsite storage of backups as a means of guaranteeing delivery on RTO.
- Retention requirements and the run-rate of new data production can aid in capacity planning.

Backup Testing

Testing has been identified as a critical success factor for the successful operation of data systems.

Backups should be tested. Recovery using backups and recovery procedures should be tested.

Backup Optimization

Overview

Backup and restore implementations can help overcome specific technical challenges that would otherwise pose a barrier to meeting business requirements.

Each of these practices represents a trade-off. Understand risks before implementing any of these practices.

Scheduling of Restore Preparation

Technical challenge: restore time

Trade-off: increased ongoing overhead for backup processing

Backup data can be prepared for restore any time after it is produced and before it is used for restore. To expedite recovery, incremental backups can be pre-applied to the prior full backup to enable faster recovery. This may be done at the expense of recovery points, or at the expense of storage by maintaining copies of unmerged full and incremental backup directories.

Moving Restored Data

Technical challenge: disk space limitations

Trade-off: modification of backup directory contents

Suggested method for moving restored data is to use `--copy-back` as this method provides added safety. Where you might instead optimize for disk space savings, system resources, and time you may choose to instead use

MariaDB Enterprise Backup's `--move-back` option. Speed benefits are only present when backup files are on the same disk partition as the destination data directory.

The `--move-back` option will result in the removal of all data files from the backup directory, so it is best to use this option only when you have an additional copy of your backup data in another location.

To restore from a backup by moving files, use the `--move-back` option:

```
mariadb-backup --move-back --target-dir=/data/backups/full
```

Multithreading

Technical challenge:: CPU bottlenecks

Trade-off: Increased workload during backups

MariaDB Enterprise Backup is a multi-threaded application that by default runs on a single thread. In cases where you have a host with multiple cores available, you can specify the number of threads you want it to use for parallel data file transfers using the `--parallel` option:

```
mariadb-backup --backup \
      --target-dir=/data/backups/full \
      --user=mariadb-backup \
      --password=mbu_passwd \
      --parallel=12
```

Incrementing an Incremental Backup

Technical challenge: Backup resource overhead, backup duration

Trade-off: Increased restore complexity, restore process duration

Under normal operation an incremental backup is taken against an existing full backup. This allows you to further shorten the amount of time MariaDB Enterprise Backup locks MariaDB Enterprise Server while copying tablespaces. You can then apply the changes in the increment to the full backup with a `--prepare` operation at leisure, without disrupting database operations.

MariaDB Enterprise Backup also supports incrementing from an incremental backup. In this operation, the `--incremental-basedir` option points not to the full backup directory but rather to the previous incremental backup.

```
mariadb-backup --backup \
      --incremental-basedir=/data/backups/inc1 \
      --target-dir=/data/backups/inc2 \
      --user=mariadb-backup \
      --password=mbu_passwd
```

In preparing a backup to restore the data directory, apply the chain of incremental backups to the full backup in order. That is, first `inc1/, then inc2/`, and so on:

```
mariadb-backup --prepare \
      --target-dir=/data/backups/full \
      --incremental-dir=/data/backups/inc1
```

```
mariadb-backup --prepare \
      --target-dir=/data/backups/full \
      --incremental-dir=/data/backups/inc2
```

Continue to apply all the incremental changes until you have applied all available to the backup. Then restore as usual:

```
mariadb-backup --copy-back --target-dir=/data/backups/full
chown -R mysql:mysql /var/lib/mysql
```

Start MariaDB Enterprise Server on the restored data directory.

Storage Snapshots

Technical challenge: Backup resource overhead, backup duration.

Trade-off: Limited to platforms with volume-level snapshots, may require crash recovery.

While MariaDB Enterprise Backups produces file-level backups, users on storage solutions may prefer to instead perform volume-level snapshots to minimize resource impact. This storage capability exists with some SAN, NAS, and volume manager platforms.

Snapshots occur point-in-time, so no preparation step is needed to ensure data is internally consistent. Snapshots occur while tablespaces are open, and a restored snapshot may need to undergo crash recovery.

Just as traditional full, incremental, and partial backups should be tested, so too should recovery from snapshots be tested on an ongoing basis.

Taking Snapshots

CURRENT

MariaDB Server includes advanced backup functionality to reduce the impact of backup operations:

1. Connect with a client and issue a `BACKUP STAGE START` statement and then a `BACKUP STAGE BLOCK_COMMIT` statement.
2. Take the snapshot.
3. Issue a `BACKUP STAGE END` statement.
4. Once the backup has been completed, remove all files which begin with the `#sql prefix`. These files are generated when `ALTER TABLE` occurs during a staged backup.
5. Retrieve, copy, or store the snapshot as is typical for your storage platform and as per business requirements to make the backup durable. This may require mounting the snapshot in some manner.

< 10.11

It is recommended to briefly prevent writes while snapshotting. Specific commands vary depending on storage platform, business requirements, and setup, but a general approach is to:

1. Connect with a client and issue a `FLUSH TABLES WITH READ LOCK` statement, leaving the client connected.
2. Take the snapshot.
3. Issue an `UNLOCK TABLES` statement, to remove the read lock.
4. Retrieve, copy, or store the snapshot as is typical for your storage platform and as per business requirements to make the backup durable. This may require mounting the snapshot in some manner.

MariaDB Enterprise Backup

Overview

Regular and reliable backups are essential to successful recovery of mission critical applications. MariaDB Enterprise Server backup and restore operations are performed using MariaDB Enterprise Backup, an enterprise-build of MariaDB Backup.

MariaDB Enterprise Backup is compatible with MariaDB Enterprise Server.

Storage Engines and Backup Types

MariaDB Backup creates a file-level backup of data from the MariaDB Community Server data directory. This backup includes temporal data, and the encrypted and unencrypted tablespaces of supported storage engines (e.g., InnoDB, MyRocks, Aria).

MariaDB Enterprise Server implements:

- Full backups, which contain all data in the database.
- Incremental backups, which contain modifications since the last backup.
- Partial backups, which contain a subset of the tables in the database.

Backup support is specific to storage engines. All supported storage engines enable full backup. The InnoDB storage engine additionally supports incremental backup.

Note: MariaDB Enterprise Backup does not support backups of MariaDB ColumnStore. Backup of MariaDB ColumnStore can be performed using MariaDB ColumnStore Tools. Backup of data ingested to MariaDB ColumnStore can also occur pre-ingestion, such as in the case of HTAP where backup could occur of transactional data in MariaDB Enterprise Server, and restore of data to MariaDB ColumnStore would then occur through reprocessing..

Nonblocking Backups

A feature of MariaDB Enterprise Backup and MariaDB Enterprise Server, non-blocking backups minimize workload impact during backups. When MariaDB Enterprise Backup connects to MariaDB Enterprise Server, staging operations are initiated to protect data during read.

Non-blocking backup functionality differs from historical backup functionality in the following ways:

- MariaDB Enterprise Backup in MariaDB Enterprise Server includes enterprise-only optimizations to backup staging, including DDL statement tracking, which reduces lock-time during backups.
- MariaDB Backup in MariaDB Community Server 10.4 and later will block writes, log tables, and statistics.
- Older MariaDB Community Server releases used FLUSH TABLES WITH READ LOCK, which closed open tables and only allowed tables to be reopened with a read lock during the duration of backups.

Understanding Recovery

MariaDB Enterprise Backup creates complete or incremental backups of MariaDB Enterprise Server data, and is also used to restore data from backups produced using MariaDB Enterprise Backup.

Preparing Backups for Recovery

Full backups produced using MariaDB Enterprise Server are not initially point-in-time consistent, and an attempt to restore from a raw full backup will cause InnoDB to crash to protect the data.

Incremental backups produced using MariaDB Enterprise Backup contain only the changes since the last backup and cannot be used standalone to perform a restore.

To restore from a backup, you first need to prepare the backup for point-in-time consistency using the `--prepare` command:

- Running the `--prepare` command on a full backup synchronizes the tablespaces, ensuring that they are point-in-time consistent and ready for use in recovery.
- Running the `--prepare` command on an incremental backup synchronizes the tablespaces and also applies the updated data into the previous full backup, making it a complete backup ready for use in recovery.

- Running the `--prepare` command on data that is to be used for a partial restore (when restoring only one or more selected tables) requires that you also use the `--export` option to create the necessary `.cfg` files to use in recovery.

Restore Requires Empty Data Directory

When MariaDB Enterprise Backup restores from a backup, it copies or moves the backup files into the MariaDB Enterprise Server data directory, as defined by the datadir system variable.

For MariaDB Backup to safely restore data from full and incremental backups, the data directory must be empty. One way to achieve this is to move the data directory aside to a unique directory name:

1. Make sure that the Server is stopped.
2. Move the data directory to a unique name (e.g., `/var/lib/mysql-2020-01-01`) OR remove the old data directory (depending on how much space you have available).
3. Create a new (empty) data directory (e.g., `mkdir /var/lib/mysql)`.
4. Run MariaDB Backup to restore the databases into that directory.
5. Change the ownership of all the restored files to the correct system user (e.g., `chown -R mysql:mysql /var/lib/mysql`).
6. Start MariaDB Enterprise Server, which now uses the restored data directory.
7. When ready, and if you have not already done so, delete the old data directory to free disk space.

Creating the Backup User

When MariaDB Backup performs a backup operation, it not only copies files from the data directory but also connects to the running MariaDB Enterprise Server.

This connection to MariaDB Enterprise Server is used to manage locks that prevent the Server from writing to a file while being read for a backup.

MariaDB Backup establishes this connection based on the user credentials specified with the `--user` and `--password` options when performing a backup.

It is recommended that a dedicated user be created and authorized to perform backups.

> **CURRENT**
>
> MariaDB Backup requires this user to have the `RELOAD, PROCESS, LOCK TABLES,` and `REPLICATION CLIENT` privileges.
>
> ```
> CREATE USER 'mariadb-backup'@'localhost'
> IDENTIFIED BY 'mbu_passwd';
>
> GRANT RELOAD, PROCESS, LOCK TABLES, BINLOG MONITOR
> ON *.*
> TO 'mariadb-backup'@'localhost';
> ```
>
> In the above example, MariaDB Backup would run on the local system that runs MariaDB Enterprise Server. Where backups may be run against a remote server, the user authentication and authorization should be adjusted.
>
> While MariaDB Backup requires a user for backup operations, no user is required for restore operations since restores occur while MariaDB Enterprise Server is not running.
>
> **< 10.5**
>
> MariaDB Backup requires this user to have the `RELOAD, PROCESS, LOCK TABLES,` and `REPLICATION CLIENT` privileges.

```
CREATE USER 'mariadb-backup'@'localhost'
IDENTIFIED BY 'mbu_passwd';

GRANT RELOAD, PROCESS, LOCK TABLES, REPLICATION CLIENT
ON *.*
TO 'mariadb-backup'@'localhost';
```

In the above example, MariaDB Backup would run on the local system that runs MariaDB Enterprise Server. Where backups may be run against a remote server, the user authentication and authorization should be adjusted.

While MariaDB Backup requires a user for backup operations, no user is required for restore operations since restores occur while MariaDB Enterprise Server is not running.

Full Backup and Restore

Full backups performed with MariaDB Backup contain all table data present in the database.

When performing a full backup, MariaDB Backup makes a file-level copy of the MariaDB Enterprise Server data directory. This backup omits log data such as the binary logs (binlog), error logs, general query logs, and slow query logs.

Performing Full Backups

When you perform a full backup, MariaDB Backup writes the backup to the `--target-dir` path. The directory must be empty or non-existent and the operating system user account must have permission to write to that directory. A database user account is required to perform the backup.

The version of `mariadb-backup` or `mariadb-backup` should be the same version as the MariaDB Enterprise Server version. When the version does not match the server version, errors can sometimes occur, or the backup can sometimes be unusable.

To create a backup, execute mariadb-backup or mariadb-backup with the `--backup` option, and provide the database user account credentials using the `--user` and `--password` options:

```
sudo mariadb-backup --backup \
      --target-dir=/data/backups/full \
      --user=mariadb-backup \
      --password=mbu_passwd
```

Subsequent to the above example, the backup is now available in the designated `--target-dir` path.

Preparing a Full Backup for Recovery

A raw full backup is not point-in-time consistent and must be prepared before it can be used for a restore. The backup can be prepared any time after the backup is created and before the backup is restored. However, MariaDB recommends preparing a backup immediately after taking the backup to ensure that the backup is consistent.

The backup should be prepared with the same version of MariaDB Backup that was used to create the backup.

To prepare the backup, execute mariadb-backup or mariadb-backup with the `--prepare` option:

```
sudo mariadb-backup --prepare \
   --use-memory=34359738368 \
   --target-dir=/data/backups/full
```

For best performance, the `--use-memory` option should be set to the server's `innodb_buffer_pool_size` value.

Restoring from Full Backups

Once a full backup has been prepared to be point-in-time consistent, MariaDB Backup is used to copy backup data to the MariaDB Enterprise Server data directory.

To restore from a full backup:

1. Stop the MariaDB Enterprise Server
2. Empty the data directory
3. Restore from the “full” directory using the `--copy-back` option:

```
mariadb-backup --copy-back --target-dir=/data/backups/full
```

MariaDB Backup writes to the data directory as the current user, which can be changed using `sudo`. To confirm that restored files are properly owned by the user that runs MariaDB Enterprise Server, run a command like this (adapted for the correct user/group):

```
chown -R mysql:mysql /var/lib/mysql
```

Once this is done, start MariaDB Enterprise Server:

```
sudo systemctl start mariadb
```

When the Server starts, it works from the restored data directory.

Incremental Backup and Restore

Full backups of large data-sets can be time-consuming and resource-intensive. MariaDB Backup supports the use of incremental backups to minimize this impact.

While full backups are resource-intensive at time of backup, the resource burden around incremental backups occurs when preparing for restore. First, the full backup is prepared for restore, then each incremental backup is applied.

Performing Incremental Backups

When you perform an incremental backup, MariaDB Backup compares a previous full or incremental backup to what it finds on MariaDB Community Server. It then creates a new backup containing the incremental changes.

Incremental backup is supported for InnoDB tables. Tables using other storage engines receive full backups even during incremental backup operations.

To increment a full backup, use the `--incremental-basedir` option to indicate the path to the full backup and the `--target-dir` option to indicate where you want to write the incremental backup:

```
mariadb-backup --backup \
      --incremental-basedir=/data/backups/full \
      --target-dir=/data/backups/inc1 \
      --user=mariadb-backup \
      --password=mbu_passwd
```

In this example, MariaDB Backup reads the `/data/backups/full directory`, and MariaDB Enterprise Server then creates an incremental backup in the `/data/backups/inc1` directory.

Preparing an Incremental Backup

An incremental backup must be applied to a prepared full backup before it can be used in a restore operation. If you have multiple full backups to choose from, pick the nearest full backup prior to the incremental backup that you want

to restore. You may also want to back up your full-backup directory, as it are modified by the updates in the incremental data.

If your full backup directory is not yet prepared, run this to make it consistent:

```
mariadb-backup --prepare --target-dir=/data/backups/full
```

Then, using the prepared full backup, apply the first incremental backup's data to the full backup in an incremental preparation step:

```
mariadb-backup --prepare \
      --target-dir=/data/backups/full \
      --incremental-dir=/data/backups/inc1
```

Once the incremental backup has been applied to the full backup, the full backup directory contains the changes from the incremental backup (that is, the inc1/ directory). Feel free to remove inc1/ to save disk space.

Restoring from Incremental Backups

Once you have prepared the full backup directory with all the incremental changes you need (as described above), stop the MariaDB Community Server, Empty its data directory, and restore from the original full backup directory using the –copy-back option:

```
mariadb-backup --copy-back --target-dir=/data/backups/full
```

MariaDB Backup writes files into the data directory using either the current user or root (in the case of a sudo operation), which may be different from the system user that runs the database. Run the following to recursively update the ownership of the restored files and directories:

```
chown -R mysql:mysql /var/lib/mysql
```

Then, start MariaDB Enterprise Server. When the Server starts, it works from the restored data directory.

Partial Backup and Restore

In a partial backup, MariaDB Backup copies a specified subset of tablespaces from the MariaDB Enterprise Server data directory. Partial backups are useful in establishing a higher frequency of backups on specific data, at the expense of increased recovery complexity. In selecting tablespaces for a partial backup, please consider referential integrity.

Performing a Partial Backup

Command-line options can be used to narrow the set of databases or tables to be included within a backup:

Option	Description
`--databases`	List of databases to include
`--databases-exclude`	List of databases to omit from the backup
`--databases-file`	Path to file listing the databases to include
`--tables`	List of tables to include
`--tables-exclude`	List of tables to exclude
`--tables-file`	Path to file listing the tables to include

For example, you may wish to produce a partial backup, which excludes a specific database:

```
mariadb-backup --backup \
      --target-dir=/data/backups/part \
      --user=mariadb-backup \
      --password=mbu_passwd \
      --database-exclude=test
```

Partial backups can also be incremental:

```
mariadb-backup --backup \
      --incremental-basedir=/data/backups/part \
      --target-dir=/data/backups/part_inc1 \
      --user=mariadb-backup \
      --password=mbu_passwd  \
      --database-exclude=test
```

Preparing a Backup Before a Partial Restore

As with full and incremental backups, partial backups are not point-in-time consistent. A partial backup must be prepared before it can be used for recovery.

A partial restore can be performed from a full backup or partial backup.

The preparation step for either partial or full backup restoration requires the use of transportable tablespaces for InnoDB. As such, each prepare operation requires the –export option:

```
mariadb-backup --prepare --export --target-dir=/data/backups/part
```

When using a partial incremental backup for restore, the incremental data must be applied to its prior partial backup data before its data is complete. If performing partial incremental backups, run the prepare statement again to apply the incremental changes onto the partial backup that served as the base.

```
mariadb-backup --prepare --export \
      --target-dir=/data/backups/part \
      --incremental-dir=/data/backups/part_inc1
```

Performing a Partial Restore

Unlike full and incremental backups, you cannot restore partial backups directly using MariaDB Backup. Further, as a partial backup does not contain a complete data directory, you cannot restore MariaDB Community Server to a startable state solely with a partial backup.

To restore from a partial backup, you need to prepare a table on the MariaDB Community Server, then manually copy the files into the data directory.

The details of the restore procedure depend on the characteristics of the table:

- Partial Restore Non-partitioned Tables
- Partial Restore Partitioned Tables
- Partial Restore of Tables with Full-Text Indexes

As partial restores are performed while the server is running, not stopped, care should be taken to prevent production workloads during restore activity.

Note: You can also use data from a full backup in a partial restore operation if you have prepared the data using the `--export` option as described above.

Partial Restore Nonpartitioned Tables

To restore a non-partitioned table from a backup, first create a new table on MariaDB Community Server to receive the restored data. It should match the specifications of the table you're restoring.

Be extra careful if the backup data is from a server with a different version than the restore server, as some differences (such as a differing `ROW_FORMAT`) can cause an unexpected result.

1. Create an empty table for the data being restored:

```
CREATE TABLE test.address_book (
   id INT PRIMARY KEY AUTO_INCREMENT,
   name VARCHAR(255),
   email VARCHAR(255));
```

2. Modify the table to discard the tablespace:

```
ALTER TABLE test.address_book DISCARD TABLESPACE;
```

3. You can copy (or move) the files for the table from the backup to the data directory:

```
# cp /data/backups/part_inc1/test/address_book.* /var/lib/mysql/test
```

4. Use a wildcard to include both the .ibd and .cfg files. Then, change the owner to the system user running MariaDB Community Server:

```
# chown mysql:mysql /var/lib/mysql/test/address_book.*
```

5. Lastly, import the new tablespace:

```
ALTER TABLE test.address_book IMPORT TABLESPACE;
```

MariaDB Community Server looks in the data directory for the tablespace you copied in, then imports it for use. If the table is encrypted, it also looks for the encryption key with the relevant key ID that the table data specifies.

6. Repeat this step for every table you wish to restore.

Partial Restore Partitioned Tables

Restoring a partitioned table from a backup requires a few extra steps compared to restoring a non-partitioned table.

To restore a partitioned table from a backup, first create a new table on MariaDB Community Server to receive the restored data. It should match the specifications of the table you're restoring, including the partition specification.

Be extra careful if the backup data is from a server with a different version than the restore server, as some differences (such as a differing ROW_FORMAT) can cause an unexpected result.

1. Create an empty table for the data being restored:

```
CREATE TABLE test.students (
   id INT PRIMARY KEY AUTO_INCREMENT
   name VARCHAR(255),
   email VARCHAR(255),
   graduating_year YEAR)
PARTITION BY RANGE (graduating_year) (
   PARTITION p9 VALUES LESS THAN 2019
   PARTITION p1 VALUES LESS THAN MAXVALUE
);
```

2. Then create a second empty table matching the column specification, but without partitions. This is your working table:

```
CREATE TABLE test.students_work AS
SELECT * FROM test.students WHERE NULL;
```

3. For each partition you want to restore, discard the working table's tablespace:

```
ALTER TABLE test.students_work DISCARD TABLESPACE;
```

4. Then, copy the table files from the backup, using the new name:

```
# cp /data/backups/part_inc1/test/students.ibd /var/lib/mysql/test/students_work.ibd
# cp /data/backups/part_inc1/test/students.cfg /var/lib/mysql/test/students_work.cfg
```

5. Change the owner to that of the user running MariaDB Community Server:

```
# chown mysql:mysql /var/lib/mysql/test/students_work.*
```

6. Import the copied tablespace:

```
ALTER TABLE test.students_work IMPORT TABLESPACE;
```

7. Lastly, exchange the partition, copying the tablespace from the working table into the partition file for the target table:

```
ALTER TABLE test.students EXCHANGE PARTITION p0 WITH TABLE test.students_work;
```

8. Repeat the above process for each partition until you have them all exchanged into the target table. Then delete the working table, as it's no longer necessary:

```
DROP TABLE test.students_work;
```

This restores a partitioned table.

Partial Restore of Tables with Full-Text Indexes

When restoring a table with a full-text search (FTS) index, InnoDB may throw a schema mismatch error.

In this case, to restore the table, it is recommended to:

- Remove the corresponding .cfg file.
- Restore data to a table without any secondary indexes including FTS.
- Add the necessary secondary indexes to the restored table.

For example, to restore table t1 with FTS index from database db1:

1. In the MariaDB shell, drop the table you are going to restore:

```
DROP TABLE IF EXISTS db1.t1;
```

2. Create an empty table for the data being restored:

```
CREATE TABLE db1.t1(f1 CHAR(10)) ENGINE=INNODB;
```

3. Modify the table to discard the tablespace:

```
ALTER TABLE db1.t1 DISCARD TABLESPACE;
```

4. In the operating system shell, copy the table files from the backup to the data directory of the corresponding database:

```
$ sudo cp /data/backups/part/db1/t1.* /var/lib/mysql/db1
```

5. Remove the .cfg file from the data directory:

```
$ sudo rm /var/lib/mysql/db1/t1.cfg
```

6. Change the owner of the newly copied files to the system user running MariaDB Community Server:

```
$ sudo chown mysql:mysql /var/lib/mysql/db1/t1.*
```

7. In the MariaDB shell, import the copied tablespace:

```
ALTER TABLE db1.t1 IMPORT TABLESPACE;
```

8. Verify that the data has been successfully restored:

```
SELECT * FROM db1.t1;
```

```
+--------+
| f1     |
+--------+
| ABC123 |
+--------+
```

9. Add the necessary secondary indexes:

```
ALTER TABLE db1.t1 FORCE, ADD FULLTEXT INDEX f_idx(f1);
```

10. The table is now fully restored:

```
SHOW CREATE TABLE db1.t1\G
```

```
*************************** 1. row ***************************
       Table: t1
Create Table: CREATE TABLE `t1` (
  `f1` char(10) DEFAULT NULL,
  FULLTEXT KEY `f_idx` (`f1`)
) ENGINE=InnoDB DEFAULT CHARSET=utf8mb4 COLLATE=utf8mb4_general_ci
```

Point-in-Time Recoveries

Point-in-time recovery (PITR) is documented here.

mariadb-backup Overview

> **Note:**
>
> mariadb-backup was previously called mariabackup.

mariadb-backup is an open source tool provided by MariaDB for performing physical online backups of InnoDB, Aria and MyISAM tables. For InnoDB, “hot online” backups are possible. It was originally forked from Percona XtraBackup 2.3.8. It is available on Linux and Windows.

This tool provides a production-quality, nearly non-blocking method for performing full backups on running systems. While partial backups with mariadb-backup are technically possible, they require many steps and cannot be restored directly onto existing servers containing other data.

Supported Features

`mariadb-backup` supports all of the main features of Percona XtraBackup 2.3.8, plus:

- Backup/Restore of tables using Data-at-Rest Encryption.
- Backup/Restore of tables using InnoDB Page Compression.
- mariadb-backup SST method with Galera Cluster.
- Microsoft Windows support.
- Backup/Restore of tables using the MyRocks storage engine. See Files Backed up by mariadb-backup: MyRocks Data Files for more information.

Supported Features in MariaDB Enterprise Backup

> **CURRENT**
>
> MariaDB Backup supports some additional features, such as:

- Minimizes locks during the backup to permit more concurrency and to enable faster backups.
  - This relies on the usage of `BACKUP STAGE` commands and DDL logging.
  - This includes no locking during the copy phase of `ALTER TABLE` statements, which tends to be the longest phase of these statements.
- Provides optimal backup support for all storage engines that store things on local disk.

< 10.11.8

MariaDB Backup does **not** support some additional features.

Backup Types

mariadb-backup supports various type of backups (and restores from those backups), documented on separate pages:

- Full backup and restore
- Incremental backup and restore
- Partial backup and restore
- Restoring individual databases, tables, and partitions
- Point-in-time recovery (PITR)

Installing `mariadb-backup`

Installing on Linux

The `mariadb-backup` executable is included in binary tarballs on Linux.

Installing with a Package Manager

mariadb-backup can also be installed via a package manager on Linux. Many Linux distributions provide MariaDB software "out of the box", including `mariadb-backup`. If your Linux distribution doesn't, however, you can install using a MariaDB repository.

In order to do so, your system needs to be configured to install from one of the MariaDB repositories.

You can configure your package manager to install it from MariaDB Corporation's MariaDB Package Repository by using the MariaDB Package Repository setup script.

You can also configure your package manager to install it from MariaDB Foundation's MariaDB Repository by using the MariaDB Repository Configuration Tool.

Installing with yum/dnf

On RHEL, CentOS, Fedora, and other similar Linux distributions, it is highly recommended to install the relevant RPM package from MariaDB's repository using yum or dnf. Starting with RHEL 8 and Fedora 22, `yum` has been replaced by `dnf`, which is the next major version of `yum`. However, `yum` commands still work on many systems that use `dnf`. For example:

```
sudo yum install MariaDB-backup
```

Installing with apt-get

On Debian, Ubuntu, and other similar Linux distributions, it is highly recommended to install the relevant DEB package from MariaDB's repository using apt-get. For example:

```
sudo apt-get install mariadb-backup
```

Installing with zypper

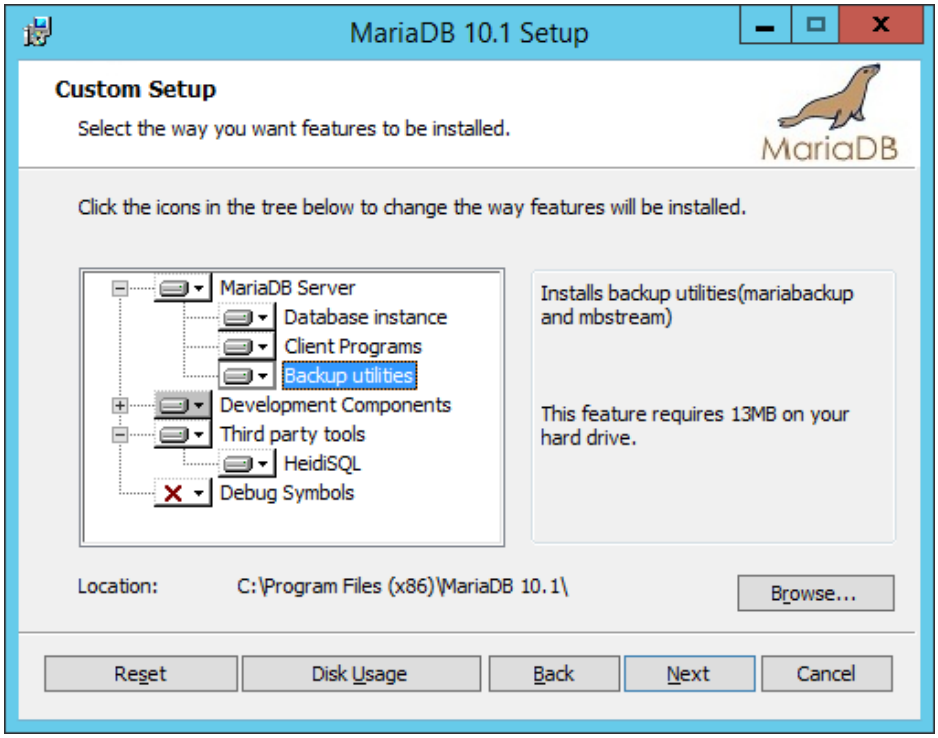
On SLES, OpenSUSE, and other similar Linux distributions, it is highly recommended to install the relevant RPM package from MariaDB's repository using zypper. For example:

```
sudo zypper install MariaDB-backup
```

Installing on Windows

The `mariadb-backup` executable is included in MSI and ZIP packages on Windows.

When using the Windows MSI installer, `mariadb-backup` can be installed by selecting *Backup utilities*:



MariaDB MSI Installer showing the Backup utilities install option

Usage

The command to use `mariadb-backup` and the general syntax is:

```
mariadb-backup <options>
```

For in-depth explanations on how to use `mariadb-backup`, see:

- Full Backup and Restore with mariadb-backup
- Incremental Backup and Restore with mariadb-backup
- Partial Backup and Restore with mariadb-backup
- Restoring Individual Tables and Partitions with mariadb-backup
- Setting up a Replica with mariadb-backup
- Using Encryption and Compression Tools With mariadb-backup

Options

Options supported by mariadb-backup can be found on the mariadb-backup Options page.

Warning:

`mariadb-backup` will currently silently ignore unknown command-line options, so be extra careful about accidentally including typos in options or accidentally using options from later `mariadb-backup` versions. The reason for this is that `mariadb-backup` currently treats command-line options and options from option files equivalently. When it reads from these option files, it has to read a lot of options from the server option groups read by mariadbd. However, `mariadb-backup` does not know about many of the options that it normally reads in these option groups. If `mariadb-backup` raised an error or warning when it encountered an unknown option, then this process would generate a large amount of log messages under normal use. Therefore, `mariadb-backup` is designed to silently ignore the unknown options instead. See MDEV-18215 about that.

Option Files

In addition to reading options from the command-line, mariadb-backup can also read options from option files.

The following options relate to how MariaDB command-line tools handles option files. They must be given as the first argument on the command-line:

Option	Description
`--print-defaults`	Print the program argument list and exit.
`--no-defaults`	Don't read default options from any option file.
`--defaults-file=#`	Only read default options from the given option file.
`--defaults-extra-file=#`	Read this file after the global files are read.
`--defaults-group-suffix=#`	In addition to the default option groups, also read option groups with this suffix.

Server Option Groups

mariadb-backup reads server options from the following option groups from option files:

Group	Description
`[mariadb-backup]`	Options read by `mariadb-backup`.
`[mariadb-backup]`	Options read by `mariadb-backup`.
`[xtrabackup]`	Options read by `mariadb-backup` and Percona XtraBackup.
`[server]`	Options read by MariaDB Server.
`[mysqld]`	Options read by `mariadbd`, which includes both MariaDB Server and MySQL Server (where it is called `mysqld`).
`[mysqld-X.Y]`	Options read by a specific version of mysqld, which includes both MariaDB Server and MySQL Server. For example: `[mysqld-10.6]`.
`[mariadb]`	Options read by MariaDB Server.
`[mariadb-X.Y]`	Options read by a specific version of MariaDB Server. For example: `[mariadb-10.6]`.
`[mariadbd]`	Options read by MariaDB Server. Available from MariaDB 10.5.4.
`[mariadbd-X.Y]`	Options read by a specific version of MariaDB Server. For example: `[mariadbd-10.6]`. Available from MariaDB 10.5.4.

Group	Description
`[client-server]`	Options read by all MariaDB client programs and the MariaDB Server. This is useful for options like socket and port, which is common between the server and the clients.
`[galera]`	Options read by MariaDB Server, but only if it is compiled with Galera Cluster support. All builds on Linux are compiled with Galera Cluster support. When using one of these builds, options from this option group are read even if the Galera Cluster functionality is not enabled.

Client Option Groups

mariadb-backup reads client options from the following option groups from option files:

Group	Description
`[mariadb-backup]`	Options read by mariadb-backup. Available starting with MariaDB 10.1.31 and MariaDB 10.2.13.
`[mariadb-backup]`	Options read by mariadb-backup. Available starting with MariaDB 10.4.14 and MariaDB 10.5.4
`[xtrabackup]`	Options read by mariadb-backup and Percona XtraBackup.
`[client]`	Options read by all MariaDB and MySQL client programs, which includes both MariaDB and MySQL clients. For example, mysqldump.
`[client-server]`	Options read by all MariaDB client programs and the MariaDB Server. This is useful for options like socket and port, which is common between the server and the clients. Available starting with MariaDB 10.1.38, MariaDB 10.2.22, and MariaDB 10.3.13.
`[client-mariadb]`	Options read by all MariaDB client programs. Available starting with MariaDB 10.1.38, MariaDB 10.2.22, and MariaDB 10.3.13.

Backup History Table

`mariadb-backup` can optionally track your backup operations in a database table. This provides a centralized audit log and allows you to automate incremental backups by referencing the logical name of the previous backup instead of managing file paths.

Table Location and Schema Changes (MariaDB 10.11):

- **MariaDB 10.11 and later:** The history table is `mysql.mariadb_backup_history` and uses the **InnoDB** storage engine (transactional).
- **MariaDB 10.10 and earlier:** The history table is `PERCONA_SCHEMA.xtrabackup_history` and uses the **CSV** storage engine.

> **Note:**
>
> On the first run after upgrading to MariaDB 10.11, `mariadb-backup` will attempt to migrate the old CSV table to the new InnoDB table. This requires specific privileges (see below).

Authentication and Privileges

`mariadb-backup` needs to authenticate with the database server when it performs a backup operation (i.e. when the –backupoption is specified). For most use cases, the user account that performs the backup needs to have the following global privileges on the database server.

> **CURRENT**
>
> The required privileges are:

```
CREATE USER 'mariadb-backup'@'localhost' IDENTIFIED BY 'mypassword';
GRANT RELOAD, PROCESS, LOCK TABLES, BINLOG MONITOR ON *.* TO 'mariadb-backup'@'localhost';
```

< 10.5

The required privileges are:

```
CREATE USER 'mariadb-backup'@'localhost' IDENTIFIED BY 'mypassword';
GRANT RELOAD, PROCESS, LOCK TABLES, REPLICATION CLIENT ON *.* TO 'mariadb-backup'@'localhost';
```

If your database server is also using the MyRocks storage engine, then the user account that performs the backup will also need the `SUPER` global privilege. This is because `mariadb-backup` creates a checkpoint of this data by setting the rocksdb_create_checkpoint system variable, which requires this privilege. See MDEV-20577 for more information.

`CONNECTION ADMIN` is also required where –kill-long-queries-timeout is greater than `0`, and –no-lock isn't applied in order to KILL queries.

`REPLICA MONITOR` (or alias `SLAVE MONITOR`) is also required where –galera-info or –slave-info is specified.

To use the –history option(or the incremental history options), the backup user requires specific privileges on the history table.

CURRENT

The user needs `INSERT` to create history records and `SELECT` to read them for incremental backups:

```
GRANT SELECT, INSERT, CREATE, ALTER ON mysql.mariadb_backup_history TO 'mariadb-backup'@'localhost';
```

< MARIADB 10.10

The user needs privileges on the legacy `PERCONA_SCHEMA`:

```
GRANT SELECT, INSERT, CREATE, ALTER ON PERCONA_SCHEMA.xtrabackup_history TO 'mariadb-
backup'@'localhost';
```

For Upgrading to 10.11 (One-Time Migration)

If upgrading from an older version, `mariadb-backup` will attempt to migrate the old table to the new location on the first run. The backup user needs privileges to move and modify the old table:

```
GRANT DROP, ALTER, RENAME ON PERCONA_SCHEMA.xtrabackup_history TO 'mariadb-backup'@'localhost';
GRANT CREATE ON PERCONA_SCHEMA TO 'mariadb-backup'@'localhost';
```

Alternatively, you can perform this migration manually before running the backup:

```
RENAME TABLE PERCONA_SCHEMA.xtrabackup_history TO mysql.mariadb_backup_history;
ALTER TABLE mysql.mariadb_backup_history ENGINE=InnoDB;
```

The user account information can be specified with the –user and –password command-line options. For example:

```
mariadb-backup --backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

The user account information can also be specified in a supported client option group in an option file. For example:

```
[mariadb-backup]
user=mariadb-backup
password=mypassword
```

`mariadb-backup` does not need to authenticate with the database server when preparing or restoring a backup.

File System Permissions

`mariadb-backup` has to read MariaDB's files from the file system. Therefore, when you run `mariadb-backup` as a specific operating system user, you should ensure that user account has sufficient permissions to read those files.

If you are using Linux and if you installed MariaDB with a package manager, then MariaDB's files will probably be owned by the `mysql` user and the `mysql` group.

Using `mariadb-backup` with Data-at-Rest Encryption

`mariadb-backup` supports Data-at-Rest Encryption.

mariadb-backup will query the server to determine which key management and encryption plugin is being used, and then it will load that plugin itself, which means that `mariadb-backup` needs to be able to load the key management and encryption plugin's shared library.

mariadb-backup will also query the server to determine which encryption keys it needs to use.

In other words, `mariadb-backup` is able to figure out a lot of encryption-related information on its own, so normally one doesn't need to provide any extra options to backup or restore encrypted tables.

`mariadb-backup` backs up encrypted and unencrypted tables as they are on the original server. If a table is encrypted, then the table will remain encrypted in the backup. Similarly, if a table is unencrypted, then the table will remain unencrypted in the backup.

The primary reason that mariadb-backup needs to be able to encrypt and decrypt data is that it needs to apply InnoDB redo log records to make the data consistent when the backup is prepared. As a consequence, mariadb-backup does not perform many encryption or decryption operations when the backup is initially taken. MariaDB performs more encryption and decryption operations when the backup is prepared. This means that some encryption-related problems (such as using the wrong encryption keys) may not become apparent until the backup is prepared.

Using `mariadb-backup` for Galera SSTs

The `mariadb-backup` SST method uses the `mariadb-backup` utility for performing SSTs. See mariadb-backup SST method for more information.

Files Backed up by `mariadb-backup`

`mariadb-backup` backs up many different files in order to perform its backup operation. See Files Backed up by mariadb-backup for a list of these files.

Files Created by `mariadb-backup`

`mariadb-backup` creates several different types of files during the backup and prepare phases. See Files Created by mariadb-backup for a list of these files.

Binary Logs

`mariadb-backup` can store the binary log position in the backup. See –binlog-info. This can be used for point-in-time recovery and to use the backup to setup a slave with the correct binlog position.

Known Issues

No Default Data Directory

`mariadb-backup` defaults to the server's default `datadir` value. See MDEV-12956 for more information.

Too Many Open Files

If `mariadb-backup` uses more file descriptors than the system is configured to allow, then users can see errors like the following:

```
2019-02-12 09:48:38 7ffff7fdb820  InnoDB: Operating system error number 23 in a file operation.
InnoDB: Error number 23 means 'Too many open files in system'.
InnoDB: Some operating system error numbers are described at
InnoDB: http://dev.mysql.com/doc/refman/5.6/en/operating-system-error-codes.html
InnoDB: Error: could not open single-table tablespace file ./db1/tab1.ibd
InnoDB: We do not continue the crash recovery, because the table may become
InnoDB: corrupt if we cannot apply the log records in the InnoDB log to it.
InnoDB: To fix the problem and start mysqld:
InnoDB: 1) If there is a permission problem in the file and mysqld cannot
InnoDB: open the file, you should modify the permissions.
InnoDB: 2) If the table is not needed, or you can restore it from a backup,
InnoDB: then you can remove the .ibd file, and InnoDB will do a normal
InnoDB: crash recovery and ignore that table.
InnoDB: 3) If the file system or the disk is broken, and you cannot remove
InnoDB: the .ibd file, you can set innodb_force_recovery > 0 in my.cnf
InnoDB: and force InnoDB to continue crash recovery here.
```

`mariadb-backup` throws an error and aborts when this error is encountered. See MDEV-19060 for more information.

When this error is encountered, one solution is to explicitly specify a value for the –open-files-limit option either on the command line or in one of the supported server option group s in an option file. For example:

```
[mariadb-backup]
open_files_limit=65535
```

An alternative solution is to set the soft and hard limits for the user account that runs `mariadb-backup` by adding new limits to /etc/security/limits.conf. For example, if `mariadb-backup` is run by the `mysql` user, then you could add lines like the following:

```
mysql soft nofile 65535
mysql hard nofile 65535
```

After the system is rebooted, the above configuration should set new open file limits for the `mysql` user, and the user's `ulimit` output should look like the following:

```
ulimit -Sn
65535
ulimit -Hn
65535
```

mariadb-backup Options

> **Note:**
>
> mariadb-backup was previously called mariabackup.

`mariadb-backup` Options (mariabackup)

Use this page as a reference for **`mariadb-backup` / `mariabackup` command-line options**. It focuses on the options (flags) you use for **physical (file-based) MariaDB backups**, including **hot online backups** for InnoDB.

Quick Reference (Most Searched Options)

- Take a physical backup: `--backup` + `--target-dir`
- Prepare a backup: `--prepare` (or legacy `--apply-log`)
- Restore a backup: `--copy-back` or `--move-back`
- Incremental backups: `--incremental-basedir` + `--incremental-dir`
- Replication/Galera metadata: `--slave-info`, `--binlog-info`, `--galera-info`
- Stream output (pipes to gzip/gpg/etc): `--stream` + `--extra-lsndir`

Common Command Patterns

Full backup (physical):

```
mariadb-backup --backup --target-dir=/backups/full \
  --user=mariadb-backup --password=...
```

Prepare (make files consistent for restore):

```
mariadb-backup --prepare --target-dir=/backups/full
```

Restore:

```
mariadb-backup --copy-back --target-dir=/backups/full
```

Incremental backup (delta against an existing base backup):

```
mariadb-backup --backup --target-dir=/backups/inc1 \
  --incremental-basedir=/backups/full
```

Options

`--apply-log`

Prepares an existing backup to restore to the MariaDB Server. This is only valid in `innobackupex` mode, which can be enabled with the –innobackupex option.

Files that `mariadb-backup` generates during –backup operations in the target directory are not ready for use on the Server. Before you can restore the data to MariaDB, you first need to prepare the backup.

In the case of full backups, the files are not point in time consistent, since they were taken at different times. If you try to restore the database without first preparing the data, InnoDB rejects the new data as corrupt. Running `mariadb-backup` with the –prepare command readies the data so you can restore it to MariaDB Server. When working with incremental backups, you need to use the `--prepare` command and the –incremental-dir option to update the base backup with the deltas from an incremental backup.

```
mariadb-backup --innobackupex --apply-log
```

Once the backup is ready, you can use the –copy-back or the –move-back commands to restore the backup to the server.

`--apply-log-only`

If this option is used when preparing a backup, then only the redo log apply stage are performed, and other stages of crash recovery are ignored. This option is used with incremental backups.

> **Important:**
>
> **Note:** This option is not needed or supported anymore.

`--backup`

Backs up your databases.

Using this command option, `mariadb-backup` performs a backup operation on your database or databases. The backups are written to the target directory, as set by the –target-dir option.

```
mariadb-backup --backup
      --target-dir /path/to/backup \
      --user user_name --password user_passwd
```

`mariadb-backup` can perform full and incremental backups. A full backup creates a snapshot of the database in the target directory. An incremental backup checks the database against a previously taken full backup, (defined by the –incremental-basedir option) and creates delta files for these changes.

In order to restore from a backup, you first need to run `mariadb-backup` with the `--prepare` option, to make a full backup point-in-time consistent or to apply incremental backup deltas to base. Then you can run `mariadb-backup` again with either the –copy-back or –move-back commands to restore the database.

For more information, see Full Backup and Restore and Incremental Backup and Restore.

`--binlog-info`

Defines how `mariadb-backup` retrieves the binary log coordinates from the server.

```
--binlog-info[=OFF | ON | LOCKLESS | AUTO]
```

The `--binlog-info` option supports the following retrieval methods. When no retrieval method is provided, it defaults to `AUTO`.

Option	Description
`OFF`	Disables the retrieval of binary log information
`ON`	Enables the retrieval of binary log information, performs locking where available to ensure consistency
`LOCKLESS`	Unsupported option
`AUTO`	Enables the retrieval of binary log information using `ON` or `LOCKLESS` where supported

Using this option, you can control how `mariadb-backup` retrieves the server's binary log coordinates corresponding to the backup.

When enabled, whether using `ON` or `AUTO`, `mariadb-backup` retrieves information from the binlog during the backup process. When disabled with `OFF`, `mariadb-backup` runs without attempting to retrieve binary log information. You may find this useful when you need to copy data without metadata like the binlog or replication coordinates.

```
mariadb-backup --binlog-info --backup
```

Currently, the `LOCKLESS` option depends on features unsupported by MariaDB Server. See the description of the xtrabackup_binlog_pos_innodb file for more information. If you attempt to run `mariadb-backup` with this option, then it causes the utility to exit with an error.

`--close-files`

Defines whether you want to close file handles.

Using this option, you can tell `mariadb-backup` that you want to close file handles. Without this option, `mariadb-backup` keeps files open in order to manage DDL operations. When working with particularly large tablespaces, closing the file can make the backup more manageable. However, it can also lead to inconsistent backups. Use at your own risk.

```
mariadb-backup --close-files --prepare
```

`--compress`

> **Warning:**
>
> This option was deprecated as it relies on the no longer maintained QuickLZ library. It are removed in a future release - versions supporting this function will not be affected. It is recommended to instead backup to a stream (stdout), and use a 3rd party compression library to compress the stream, as described in Using Encryption and Compression Tools With mariadb-backup.

Defines the compression algorithm for backup files.

```
--compress[=compression_algorithm]
```

The `--compress` option only supports the now deprecated `quicklz` algorithm.

Option	Description
`quicklz`	Uses the QuickLZ compression algorithm

```
mariadb-backup --compress --backup
```

If a backup is compressed using this option, then `mariadb-backup` will record that detail in the xtrabackup_info file.

`--compress-chunk-size`

> **Warning:**
>
> Deprecated, for details see the –compress option.

Defines the working buffer size for compression threads.

```
--compress-chunk-size=#
```

`mariadb-backup` can perform compression operations on the backup files before writing them to disk. It can also use multiple threads for parallel data compression during this process. Using this option, you can set the chunk size each thread uses during compression. It defaults to `64K`.

```
mariadb-backup --backup --compress \
     --compress-threads=12 --compress-chunk-size=5M
```

To further configure backup compression, see the –compress and –compress-threads options.

`--compress-threads`

> **Warning:**
>
> Deprecated, for details see the –compress option.

Defines the number of threads to use in compression.

```
--compress-threads=#
```

`mariadb-backup` can perform compression operations on the backup files before writing them to disk. Using this option, you can define the number of threads you want to use for this operation. You may find this useful in speeding up the compression of particularly large databases. It defaults to single-threaded.

```
mariadb-backup --compress --compress-threads=12 --backup
```

To further configure backup compression, see the –compress and –compress-chunk-size options.

`--copy-back`

Restores the backup to the data directory.

Using this command, `mariadb-backup` copies the backup from the target directory to the data directory, as defined by the `--datadir` option. You must stop the MariaDB Server before running this command. The data directory must be empty. If you want to overwrite the data directory with the backup, use the `--force-non-empty-directories` option.

Bear in mind, before you can restore a backup, you first need to run mariadb-backup with the –prepare option. In the case of full backups, this makes the files point-in-time consistent. With incremental backups, this applies the deltas to the base backup. Once the backup is prepared, you can run `--copy-back` to apply it to MariaDB Server.

```
mariadb-backup --copy-back --force-non-empty-directories
```

Running the `--copy-back` command copies the backup files to the data directory. Use this command if you want to save the backup for later. If you don't want to save the backup for later, use the `--move-back` option.

`--core-file`

Defines whether to write a core file.

Using this option, you can configure `mariadb-backup` to dump its core to file in the event that it encounters fatal signals. You may find this useful for review and debugging purposes.

```
mariadb-backup --core-file --backup
```

`--databases`

Defines the databases and tables you want to back up.

```
--databases="database[.table][ database[.table] ...]"
```

Using this option, you can define the specific database or databases you want to back up. In cases where you have a particularly large database or otherwise only want to back up a portion of it, you can optionally also define the tables on the database.

```
mariadb-backup --backup \
      --databases="example.table1 example.table2"
```

In cases where you want to back up most databases on a server or tables on a database, but not all, you can set the specific databases or tables you don't want to back up using the `--databases-exclude` option.

If a backup is a partial backup, then mariadb-backup will record that detail in the `xtrabackup_info` file.

In `innobackupex` mode, which can be enabled with the `--innobackupex` option, the `--databases` option can be used as described above, or it can be used to refer to a file, just as the –databases-file option can in the normal mode.

`--databases-exclude`

Defines the databases you don't want to back up.

```
--databases-exclude="database[.table][ database[.table] ...]"
```

Using this option, you can define the specific database or databases you want to exclude from the backup process. You may find it useful when you want to back up most databases on the server or tables on a database, but would like to exclude a few from the process.

```
mariadb-backup --backup \
      --databases="example" \
      --databases-exclude="example.table1 example.table2"
```

To include databases in the backup, see the `--databases` option.

If a backup is a partial backup, then `mariadb-backup` records that detail in the `xtrabackup_info` file.

`--databases-file`

Defines the path to a file listing databases and/or tables you want to back up.

```
--databases-file="/path/to/database-file"
```

Format the databases file to list one element per line, with the following syntax:

```
database[.table]
```

In cases where you need to back up a number of databases or specific tables in a database, you may find the syntax for the `--databases` and `--databases-exclude` options a little cumbersome. Using this option you can set the path to a file listing the databases or databases and tables you want to back up.

For instance, listing the databases and tables for a backup in a file called `main-backup`:

```
cat main-backup
```

```
example1
example2.table1
example2.table2
```

```
mariadb-backup --backup --databases-file=main-backup
```

If a backup is a partial backup, `mariadb-backup` records that detail in the `xtrabackup_info` file.

`-h, --datadir`

Defines the path to the database root.

```
--datadir=PATH
```

Using this option, you can define the path to the source directory. This is the directory that `mariadb-backup` reads for the data it backs up. It should be the same as the MariaDB Server `datadir` system variable.

```
mariadb-backup --backup -h /var/lib64/mysql
```

`--debug-sleep-before-unlock`

This is a debug-only option used by the Xtrabackup test suite.

`--decompress`

Deprecated, for details see the `--compress` option.

This option requires that you have the `qpress` utility installed on your system.

Defines whether you want to decompress previously compressed backup files.

When you run mariadb-backup with the `--compress` option, it compresses the subsequent backup files, using the QuickLZ algorithm. Using this option, `mariadb-backup` decompresses the compressed files from a previous backup.

For instance, run a backup with compression:

```
mariadb-backup --compress --backup
```

Then, decompress the backup:

```
mariadb-backup --decompress
```

You can enable the decryption of multiple files at a time using the `--parallel` option. By default, mariadb-backup does not remove the compressed files from the target directory. To delete these files, use the `--remove-original` option.

`--debug-sync`

Defines the debug sync point. This option is only used by the `mariadb-backup` test suite.

`--defaults-extra-file`

Defines the path to an extra default option file.

```
--defaults-extra-file=/path/to/config
```

Using this option, you can define an extra default option file for `mariadb-backup`. Unlike `--defaults-file`, this file is read after the default option files are read, allowing you to only overwrite the existing defaults.

```
mariadb-backup --backup \
      --defaults-file-extra=addition-config.cnf \
      --defaults-file=config.cnf
```

`--defaults-file`

Defines the path to the default option file.

```
--defaults-file=/path/to/config
```

Using this option, you can define a default option file for `mariadb-backup`. Unlike the `--defaults-extra-file` option, when this option is provided, it completely replaces all default option files.

```
mariadb-backup --backup \
     --defaults-file=config.cnf
```

`--defaults-group`

Defines the option group to read in the option file.

```
--defaults-group="name"
```

In situations where you find yourself using certain `mariadb-backup` options consistently every time you call it, you can set the options in an option file. The `--defaults-group` option defines what option group `mariadb-backup` reads for its options.

Options you define from the command-line can be set in the configuration file using minor formatting changes. For instance, if you find yourself perform compression operations frequently, you might set `--compress-threads` and `--compress-chunk-size` options in this way:

```
[mariadb-backup]
compress_threads = 12
compress_chunk_size = 64K
```

Now whenever you run a backup with the `--compress` option, it always performs the compression using 12 threads and 64K chunks.

```
mariadb-backup --compress --backup
```

See mariadb-backup Overview: Server Option Groups and mariadb-backup Overview: Client Option Groups for a list of the option groups read by `mariadb-backup` by default.

`--encrypted-backup`

When this option is used with `--backup`, if `mariadb-backup` encounters a page that has a non-zero `key_version` value, then mariadb-backup assumes that the page is encrypted.

Use `--skip-encrypted-backup` instead to allow mariadb-backup to copy unencrypted tables that were originally created before MySQL 5.1.48.

`--export`

If this option is provided during the `--prepare` stage, then it tells `mariadb-backup` to create `.cfg` files for each InnoDB file-per-table tablespace. These `.cfg` files are used to import transportable tablespaces in the process of restoring partial backups and restoring individual tables and partitions.

The `--export` option could require rolling back incomplete transactions that had modified the table. This will likely create a “new branch of history” that does not correspond to the server that had been backed up, which makes it impossible to apply another incremental backup on top of such additional changes. The option should only be applied when doing a `--prepare` of the last incremental.

```
mariadb-backup --prepare --export
```

`mariadb-backup` did not support the `--export` option. See MDEV-13466 about that. In earlier versions of MariaDB, this means that mariadb-backup could not create `.cfg` files for InnoDB file-per-table tablespaces during the `--prepare` stage. You can still import file-per-table tablespaces without the `.cfg` files in many cases, so it may still be possible in those versions to restore partial backups or to restore individual tables and partitions with just the `.ibd` files. If you have a full backup and you need to create `.cfg` files for InnoDB file-per-table tablespaces, then you can do so by preparing the backup as usual without the `--export` option, and then restoring the backup, and then starting the server. At that point, you can use the server’s built-in features to copy the transportable tablespaces.

`--extra-lsndir`

Saves an extra copy of the `xtrabackup_checkpoints` and `xtrabackup_info` files into the given directory.

```
--extra-lsndir=PATH
```

When using the `--backup` option, `mariadb-backup` produces a number of backup files in the target directory. Using this option, you can have `mariadb-backup` produce additional copies of the `xtrabackup_checkpoints` and `xtrabackup_info` files in the given directory.

```
mariadb-backup --extra-lsndir=extras/ --backup
```

This is especially useful when using `--stream` for streaming output, e.g. for compression and/or encryption using external tools in combination with incremental backups, as the `xtrabackup_checkpoints` file necessary to determine the LSN to continue the incremental backup from is still accessible without uncompressing / decrypting the backup file first. Pass in the `--extra-lsndir` of the previous backup as `--incremental-basedir` .

`--force-non-empty-directories`

Allows `--copy-back` or `--move-back` options to use non-empty target directories.

When using `mariadb-backup` with the `--copy-back` or `--move-back` options, they normally require a non-empty target directory to avoid conflicts. Using this option with either of command allows `mariadb-backup` to use a non-empty directory.

```
mariadb-backup --force-non-empty-directories --copy-back
```

Bear in mind that this option does not enable overwrites. When copying or moving files into the target directory, if `mariadb-backup` finds that the target file already exists, it fails with an error.

`--ftwrl-wait-query-type`

Defines the type of query allowed to complete before `mariadb-backup` issues the global lock.

```
--ftwrl-wait-query-type=[ALL | UPDATE | SELECT]
```

The `--ftwrl-wait-query-type` option supports the following query types. The default value is `ALL` .

Option	Description
ALL	Waits until all queries complete before issuing the global lock
SELECT	Waits until SELECT statements complete before issuing the global lock
UPDATE	Waits until UPDATE statements complete before issuing the global lock

When `mariadb-backup` runs, it issues a global lock to prevent data from changing during the backup process. When it encounters a statement in the process of executing, it waits until the statement is finished before issuing the global lock. Using this option, you can modify this default behavior to ensure that it waits only for certain query types, such as for `SELECT` and `UPDATE` statements.

```
mariadb-backup --backup  \
      --ftwrl-wait-query-type=UPDATE
```

`--ftwrl-wait-threshold`

Defines the minimum threshold for identifying long-running queries for FTWRL.

```
--ftwrl-wait-threshold=#
```

When `mariadb-backup` runs, it issues a global lock to prevent data from changing during the backup process and ensure a consistent record. If it encounters statements still in the process of executing, it waits until they complete before setting the lock. Using this option, you can set the threshold at which mariadb-backup engages FTWRL[3]. When it `--ftwrl-wait-timeout` is not 0 and a statement has run for at least the amount of time given this argument, mariadb-backup waits until the statement completes or until the `--ftwrl-wait-timeout` expires before setting the global lock and starting the backup.

```
mariadb-backup --backup \
     --ftwrl-wait-timeout=90 \
     --ftwrl-wait-threshold=30
```

`--ftwrl-wait-timeout`

Defines the timeout to wait for queries before trying to acquire the global lock. The global lock refers to `BACKUP STAGE BLOCK_COMMIT`. The global lock refers to `FLUSH TABLES WITH READ LOCK` (FTWRL).

```
--ftwrl-wait-timeout=#
```

When `mariadb-backup` runs, it acquires a global lock to prevent data from changing during the backup process and ensure a consistent record. If it encounters statements still in the process of executing, it can be configured to wait until the statements complete before trying to acquire the global lock.

If the `--ftwrl-wait-timeout` is set to 0, `mariadb-backup` tries to acquire the global lock immediately without waiting. This is the default value.

If the `--ftwrl-wait-timeout` is set to a non-zero value, then `mariadb-backup` waits for the configured number of seconds until trying to acquire the global lock.

`mariadb-backup` exits if it can't acquire the global lock after waiting for the configured number of seconds.

```
mariadb-backup --backup \
      --ftwrl-wait-query-type=UPDATE \
      --ftwrl-wait-timeout=5
```

The `--ftwrl-wait-timeout` option specifies the maximum time that `mariadb-backup` will wait to obtain the global lock required to begin a consistent backup.

> **FROM MARIADB 10.4**
>
> this lock is acquired with `BACKUP STAGE BLOCK_COMMIT`.
>
> **BEFORE 10.4**
>
> this lock is acquired with `FLUSH TABLES WITH READ LOCK (FTWRL)`.

If the lock cannot be obtained within the configured timeout, the backup process fails.

This option helps avoid failures caused by long-running MariaDB queries that block backup locks.

Example Errors

When the timeout is not set appropriately, backups may fail with messages such as:

```
Unable to obtain lock. Please try again later.
```

or

```
FATAL ERROR: failed to execute query BACKUP STAGE START:
Lock wait timeout exceeded; try restarting transaction
```

Example log excerpt:

```
[00] 2022-02-08 15:43:25 Unable to obtain lock. Please try again later.
[00] 2022-02-08 15:43:25 Error on BACKUP STAGE START query execution
mariabackup: Stopping log copying thread.
```

Originally, `mariadb-backup` could wait indefinitely for the lock. Starting with the fix for MDEV-20230:

- The `--ftwrl-wait-timeout` option also ensures mariadb backup exits gracefully if the lock cannot be obtained within the timeout period.
- This prevents backups from hanging when lock acquisition is blocked by long-running queries.

When to Use

Use `--ftwrl-wait-timeout` when:

- Your workload includes long-running queries (for example, `ALTER TABLE` or large `INSERT` batches).
- Backups sometimes fail with lock wait timeout errors.
- You want `mariadb-backup` to either wait longer for the lock or exit cleanly if it cannot be obtained.

`--galera-info`

Defines whether you want to back up information about a Galera Cluster node's state.

When this option is used, mariadb-backup creates an additional file called `xtrabackup_galera_info`, which records information about a Galera Cluster node's state. It records the values of the wsrep_local_state_uuid and wsrep_last_committed status variables.

You should only use this option when backing up a Galera Cluster node. If the server is not a Galera Cluster node, then this option has no effect.

This option, when enabled and used with GTID replication, will rotate the binary logs at backup time.

```
mariadb-backup --backup --galera-info
```

`--history`

CURRENT

Defines whether you want to track backup history in the `mysql.mariadb_backup_history` table.

```
--history[=name]
```

When using this option, `mariadb-backup` records its operation in a table on the MariaDB Server. Passing a name to this option allows you group backups under arbitrary terms for later processing and analysis.

```
mariadb-backup --backup --history=backup_all
```

Information is written to `mysql.mariadb_backup_history`.

`mariadb-backup` also records this in the mariadb_backup_info file.

< 10.11

Defines whether you want to track backup history in the `PERCONA_SCHEMA.xtrabackup_history` table.

```
--history[=name]
```

When using this option, `mariadb-backup` records its operation in a table on the MariaDB Server. Passing a name to this option allows you group backups under arbitrary terms for later processing and analysis.

```
mariadb-backup --backup --history=backup_all
```

Information is written to `PERCONA_SCHEMA.xtrabackup_history`.

`mariadb-backup` also records this in the xtrabackup_info file.

`-H, --host`

Defines the hostname for the MariaDB Server you want to back up.

```
--host=name_or_ip-address
```

This option defines the hostname or IP address to use when **connecting to a local MariaDB Server over TCP/IP**. By default, `mariadb-backup` attempts to connect to `localhost`.

> **Warning:**
>
> **The mariadb-backup client cannot create backups from a remote server.** Therefore, this option does not allow you to back up a remote server. `mariadb-backup` must always be run on the same server where the database files reside. The `--host` option is used only to establish the client connection for managing locks and retrieving metadata. The actual data files are always read from the local filesystem. Attempting to use this option to back up a remote host results in a backup of the local machine's data, associated with the remote machine's binary log coordinates.

```
mariadb-backup --backup \
      --host="192.168.0.33"
```

`--include`

This option is a regular expression to be matched against table names in *`databasename.tablename`* format. It is equivalent to the `--tables` option. This is only valid in `innobackupex` mode, which can be enabled with the `--innobackupex` option.

`--incremental`

Defines whether you want to take an increment backup, based on another backup. This is only valid in `innobackupex` mode, which can be enabled with the `--innobackupex` option.

```
mariadb-backup --innobackupex --incremental
```

Using this option with the `--backup` option makes the operation incremental rather than a complete overwrite. When this option is specified, either the `--incremental-lsn` or `--incremental-basedir` options can also be given. If neither option is given, `--incremental-basedir` is used by default, set to the first timestamped backup directory in the backup base directory.

```
mariadb-backup --innobackupex --backup --incremental \
     --incremental-basedir=/data/backups \
     --target-dir=/data/backups
```

If a backup is a incremental backup, then `mariadb-backup` records that detail in the `xtrabackup_info` file.

`--incremental-basedir`

Defines whether you want to take an incremental backup, based on another backup.

```
--incremental-basedir=PATH
```

Using this option with the `--backup` option makes the operation incremental rather than a complete overwrite. `mariadb-backup` only copies pages from `.ibd` files if they are newer than the backup in the specified directory.

```
mariadb-backup --backup \
     --incremental-basedir=/data/backups \
     --target-dir=/data/backups
```

If a backup is a incremental backup, then `mariadb-backup` records that detail in the `xtrabackup_info` file.

`--incremental-dir`

Defines whether you want to take an incremental backup, based on another backup.

```
--increment-dir=PATH
```

Using this option with `--prepare` command option makes the operation incremental rather than a complete overwrite. mariadb-backup will apply `.delta` files and log files into the target directory.

```
mariadb-backup --prepare \
      --increment-dir=backups/
```

If a backup is a incremental backup, then `mariadb-backup` records that detail in the `xtrabackup_info` file.

`--incremental-force-scan`

Defines whether you want to force a full scan for incremental backups.

When using `mariadb-backup` to perform an incremental backup, this option forces it to also perform a full scan of the data pages being backed up, even when there's bitmap data on the changes. MariaDB does not support changed page bitmaps, so this option is useless in those versions. See MDEV-18985 for more information.

```
mariadb-backup --backup \
     --incremental-basedir=/path/to/target \
     --incremental-force-scan
```

`--incremental-history-name`

Defines a logical name for the backup.

```
--incremental-history-name=name
```

`mariadb-backup` can store data about its operations on the MariaDB Server. Using this option, you can define the logical name it uses in identifying the backup.

```
mariadb-backup --backup \
     --incremental-history-name=morning_backup
```

The table it uses by default is named `mysql.mariadb_backup_history`. Prior to MariaDB 10.11, the default table was `PERCONA_SCHEMA.xtrabackup_history`.

`mariadb-backup` also records this in the `xtrabackup_info` file.

`--incremental-history-uuid`

Defines a UUID for the backup.

```
--incremental-history-uuid=name
```

`mariadb-backup` can store data about its operations on the MariaDB Server. Using this option, you can define the UUID it uses in identifying a previous backup to increment from. It checks `--incremental-history-name`, `--incremental-basedir`, and `--incremental-lsn`. If mariadb-backup fails to find a valid lsn, it generates an error.

```
mariadb-backup --backup \
      --incremental-history-uuid=main-backup012345678
```

The table it uses is named `PERCONA_SCHEMA.xtrabackup_history`, but expect that name to change in future releases. See MDEV-19246 for more information.

Table Name and Schema Changes (MariaDB 10.11):

- MariaDB 10.11 and later: Uses mysql.mariadb_backup_history (InnoDB).
- MariaDB 10.10 and earlier: Uses PERCONA_SCHEMA.xtrabackup_history (CSV).

`mariadb-backup` also records this in the `xtrabackup_info` file.

`--incremental-lsn`

Defines the sequence number for incremental backups.

```
--incremental-lsn=name
```

Using this option, you can define the sequence number (LSN) value for `--backup` operations. During backups, `mariadb-backup` only copies `.ibd` pages newer than the specified values.

> **Warning:**
>
> Incorrect LSN values can make the backup unusable. It is impossible to diagnose this issue.

`--innobackupex`

> **Note:**
>
> Deprecated option.

Use to enable `innobackupex` mode, which is a compatibility mode.

```
mariadb-backup --innobackupex
```

`--innodb`

This option has no effect. Set only for MySQL option compatibility.

`--innodb-adaptive-hash-index`

Enables InnoDB Adaptive Hash Index.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option you can explicitly enable the InnoDB Adaptive Hash Index. This feature is enabled by default for mariadb-backup. If you want to disable it, use `--skip-innodb-adaptive-hash-index`.

```
mariadb-backup --backup \
      --innodb-adaptive-hash-index
```

`--innodb-autoextend-increment`

Defines the increment in megabytes for auto-extending the size of tablespace file.

```
--innodb-autoextend-increment=36
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can set the increment in megabytes for automatically extending the size of tablespace data file in InnoDB.

```
mariadb-backup --backup \
     --innodb-autoextend-increment=35
```

`--innodb-buffer-pool-filename`

Using this option has no effect. It is available to provide compatibility with the MariaDB Server.

`--innodb-buffer-pool-size`

Defines the memory buffer size InnoDB uses the cache data and indexes of the table.

```
--innodb-buffer-pool-size=124M
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can configure the buffer pool for InnoDB operations.

```
mariadb-backup --backup \
      --innodb-buffer-pool-size=124M
```

`--innodb-checksum-algorithm`

`innodb_checksum_algorithm` has been removed.

`--innodb-data-file-path`

Defines the path to individual data files.

```
--innodb-data-file-path=/path/to/file
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option you can define the path to InnoDB data files. Each path is appended to the `--innodb-data-home-dir` option.

```
mariadb-backup --backup \
     --innodb-data-file-path=ibdata1:13M:autoextend \
     --innodb-data-home-dir=/var/dbs/mysql/data
```

`--innodb-data-home-dir`

Defines the home directory for InnoDB data files.

```
--innodb-data-home-dir=PATH
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option you can define the path to the directory containing InnoDB data files. You can specific the files using the `--innodb-data-file-path` option.

```
mariadb-backup --backup \
     --innodb-data-file-path=ibdata1:13M:autoextend \
     --innodb-data-home-dir=/var/dbs/mysql/data
```

`--innodb-doublewrite`

Enables doublewrites for InnoDB tables.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. When using this option, `mariadb-backup` improves fault tolerance on InnoDB tables with a doublewrite buffer. By default, this feature is enabled. Use this option to explicitly enable it. To disable doublewrites, use the `--skip-innodb-doublewrite` option.

```
mariadb-backup --backup \
     --innodb-doublewrite
```

`--innodb-encrypt-log`

Defines whether you want to encrypt InnoDB logs.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can tell mariadb-backup that you want to encrypt logs from its InnoDB activity.

`--innodb-file-io-threads`

Defines the number of file I/O threads in InnoDB.

```
--innodb-file-io-threads=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the number of file I/O threads mariadb-backup uses on InnoDB tables.

```
mariadb-backup --backup \
     --innodb-file-io-threads=5
```

`--innodb-file-per-table`

Defines whether you want to store each InnoDB table as an `.ibd` file.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option causes mariadb-backup to store each InnoDB table as an `.ibd` file in the target directory.

`--innodb-flush-method`

Defines the data flush method. Ignored from MariaDB 11.0. For the OS-level mechanisms behind these flag names, see Storage I/O: Buffering and Persistence.

```
--innodb-flush-method=fdatasync
                     | O_DSYNC
                     | O_DIRECT
                     | O_DIRECT_NO_FSYNC
                     | ALL_O_DIRECT
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the data flush method `mariadb-backup` uses with InnoDB tables.

```
mariadb-backup --backup \
      --innodb-flush-method==_DIRECT_NO_FSYNC
```

`--innodb-io-capacity`

Defines the number of IOP's the utility can perform.

```
--innodb-io-capacity=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can limit the I/O activity for InnoDB background tasks. It should be set around the number of I/O operations per second that the system can handle, based on drive or drives being used.

```
mariadb-backup --backup \
     --innodb-io-capacity=200
```

`--innodb-log-buffer-size`

The size of the buffer that will be used for reading log during `mariadb-backup --prepare`. Ignored when using `--innodb-log-file-mmap`.

`--innodb-log-checksums`

Defines whether to include checksums in the InnoDB logs.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can explicitly set `mariadb-backup` to include checksums in the InnoDB logs. The feature is enabled by default. To disable it, use the `--skip-innodb-log-checksums` option.

```
mariadb-backup --backup \
      --innodb-log-checksums
```

`--innodb-log-checkpoint-now`

At the start of a backup, instruct the server to write out all modified pages to the data files, to minimize the size of the `ib_logfile0` that needs to be copied.

```
mariadb-backup --backup \
      --innodb-log-checkpoint-now
```

`--innodb-log-file-mmap`

> **Note:**
>
> This variable is available from MariaDB 11.4.4 and 10.11.10.

When this option is enabled, `mariadb-backup` reads the `ib_logfile0` via a memory mapping, rather than by reading into a separately allocated buffer of `--innodb-log-buffer-size`.

`--innodb-log-files-in-group`

This option has no functionality in `mariadb-backup`. It exists for MariaDB Server compatibility.

`--innodb-log-group-home-dir`

Defines the path to InnoDB log files.

```
--innodb-log-group-home-dir=PATH
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the path to InnoDB log files.

```
mariadb-backup --backup \
     --innodb-log-group-home-dir=/path/to/logs
```

`--innodb-max-dirty-pages-pct`

Defines the percentage of dirty pages allowed in the InnoDB buffer pool.

```
--innodb-max-dirty-pages-pct=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the maximum percentage of dirty, (that is, unwritten) pages that mariadb-backup allows in the InnoDB buffer pool.

```
mariadb-backup --backup \
     --innodb-max-dirty-pages-pct=80
```

`--innodb-open-files`

Defines the number of files kept open at a time.

```
--innodb-open-files=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can set the maximum number of files InnoDB keeps open at a given time during backups.

```
mariadb-backup --backup \
      --innodb-open-files=10
```

`--innodb-page-size`

Defines the universal page size.

```
--innodb-page-size=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the universal page size in bytes for `mariadb-backup`.

```
mariadb-backup --backup \
     --innodb-page-size=16k
```

`--innodb-read-io-threads`

Defines the number of background read I/O threads in InnoDB.

```
--innodb-read-io-threads=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can set the number of I/O threads MariaDB uses when reading from InnoDB.

```
mariadb-backup --backup \
      --innodb-read-io-threads=4
```

`--innodb-undo-directory`

Defines the directory for the undo tablespace files.

```
--innodb-undo-directory=PATH
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the path to the directory where you want MariaDB to store the undo tablespace on InnoDB tables. The path can be absolute.

```
mariadb-backup --backup \
     --innodb-undo-directory=/path/to/innodb_undo
```

`--innodb-undo-tablespaces`

Defines the number of undo tablespaces to use.

```
--innodb-undo-tablespaces=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can define the number of undo tablespaces you want to use during the backup.

```
mariadb-backup --backup \
      --innodb-undo-tablespaces=10
```

`--innodb-use-native-aio`

Defines whether you want to use native AI/O.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can enable the use of the native asynchronous I/O subsystem. It is only available on Linux operating systems.

```
mariadb-backup --backup \
      --innodb-use-native-aio
```

`--innodb-write-io-threads`

Defines the number of background write I/O threads in InnoDB.

```
--innodb-write-io-threads=#
```

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can set the number of background write I/O threads `mariadb-backup` uses.

```
mariadb-backup --backup \
     --innodb-write-io-threads=4
```

`--kill-long-queries-timeout`

Defines the timeout for blocking queries.

```
--kill-long-queries-timeout=#
```

When `mariadb-backup` runs, it issues a `FLUSH TABLES WITH READ LOCK` statement. It then identifies blocking queries. Using this option you can set a timeout in seconds for these blocking queries. When the time runs out, `mariadb-backup` kills the queries.

The default value is `0`, which causes `mariadb-backup` to not attempt killing any queries.

```
mariadb-backup --backup \
      --kill-long-queries-timeout=10
```

`--kill-long-query-type`

Defines the query type the utility can kill to unblock the global lock.

```
--kill-long-query-type=ALL | UPDATE | SELECT
```

When `mariadb-backup` encounters a query that sets a global lock, it can kill the query in order to free up MariaDB Server for the backup. Using this option, you can choose the types of query it kills: `SELECT`, `UPDATE`, or both set with `ALL`. The default is `ALL`.

```
mariadb-backup --backup \
      --kill-long-query-type=UPDATE
```

`--lock-ddl-per-table`

Prevents DDL for each table to be backed up by acquiring MDL lock on that.

> **Note:**
>
> Unless the `--no-lock` option is also specified, conflicting DDL queries are killed at the end of backup This is done to avoid a deadlock between `FLUSH TABLE WITH READ LOCK`, user's DDL query (`ALTER`, `RENAME`), and MDL lock on table.

`--log`

This option has no functionality. It is set to ensure compatibility with MySQL.

`--log-bin`

Defines the base name for the log sequence.

```
--log-bin[=name]
```

Using this option you, you can set the base name for `mariadb-backup` to use in log sequences.

`--log-copy-interval`

Defines the copy interval between checks done by the log copying thread.

```
--log-copy-interval=#
```

Using this option, you can define the copy interval mariadb-backup uses between checks done by the log copying thread. The given value is in milliseconds.

```
mariadb-backup --backup \
      --log-copy-interval=50
```

`--log-innodb-page-corruption`

Continue backup if InnoDB corrupted pages are found. The pages are logged in `innodb_corrupted_pages` and backup is finished with error. `--prepare` will try to fix corrupted pages. If `innodb_corrupted_pages` exists after –prepare in base backup directory, backup still contains corrupted pages and can not be considered as consistent.

`--move-back`

Restores the backup to the data directory.

Using this command, `mariadb-backup` moves the backup from the target directory to the data directory, as defined by the `--datadir` option. You must stop the MariaDB Server before running this command. The data directory must be empty. If you want to overwrite the data directory with the backup, use the `--force-non-empty-directories` option.

Bear in mind, before you can restore a backup, you first need to run `mariadb-backup` with the `--prepare` option. In the case of full backups, this makes the files point-in-time consistent. With incremental backups, this applies the deltas to the base backup. Once the backup is prepared, you can run `--move-back` to apply it to MariaDB Server.

```
mariadb-backup --move-back \
      --datadir=/var/mysql
```

Running the `--move-back` command moves the backup files to the data directory. Use this command if you don't want to save the backup for later. If you do want to save the backup for later, use the `--copy-back` option.

`--mysqld`

Used internally to prepare a backup.

`--no-backup-locks`

`mariadb-backup` locks the database by default when it runs. This option disables support for Percona Server's backup locks.

When backing up Percona Server, mariadb-backup would use backup locks by default. To be specific, backup locks refers to the `LOCK TABLES FOR BACKUP` and `LOCK BINLOG FOR BACKUP` statements. This option can be used to disable support for Percona Server's backup locks. This option has no effect when the server does not support Percona's backup locks.

Deprecated and has no effect from MariaDB 10.11.8, MariaDB 11.0.6, MariaDB 11.1.5 and MariaDB 11.2.4 as MariaDB now always uses backup locks for better performance. See MDEV-32932.

```
mariadb-backup --backup --no-backup-locks
```

`--no-lock`

Disables table locks with the `FLUSH TABLE WITH READ LOCK` statement.

Using this option causes mariadb-backup to disable table locks with the `FLUSH TABLE WITH READ LOCK` statement. Only use this option if:

- You are not executing DML statements on non-InnoDB tables during the backup. This includes the `mysql` database system tables (which are MyISAM).
- You are not executing any DDL statements during the backup.
- You are *not* using the file `xtrabackup_binlog_info`, which is not consistent with the data when `--no-lock` is used. Use the file `xtrabackup_binlog_pos_innodb` instead.
- All tables you're backing up use the InnoDB storage engine.

```
mariadb-backup --backup --no-lock
```

If you're considering `--no-lock` due to backups failing to acquire locks, this may be due to incoming replication events preventing the lock. Consider using the `--safe-slave-backup` option to momentarily stop the replica thread. This alternative may help the backup to succeed without resorting to `--no-lock`.

The `--no-lock` option only provides a consistent backup if the user ensures that no DDL or non-transactional table updates occur during the backup. The `--no-lock` option is not supported by MariaDB plc.

`--no-timestamp`

This option prevents creation of a time-stamped subdirectory of the `BACKUP-ROOT-DIR` given on the command line. When it is specified, the backup is done in `BACKUP-ROOT-DIR` instead. This is only valid in `innobackupex` mode, which can be enabled with the `--innobackupex` option.

`--no-version-check`

Disables version check.

Using this option, you can disable mariadb-backup version check.

```
mariadb-backup --backup --no-version-check
```

`--open-files-limit`

Defines the maximum number of file descriptors.

```
--open-files-limit=#
```

Using this option, you can define the maximum number of file descriptors mariadb-backup reserves with `setrlimit()`.

```
mariadb-backup --backup \
      --open-files-limit=
```

`--parallel`

Defines the number of threads to use for parallel data file transfer.

```
--parallel=#
```

Using this option, you can set the number of threads mariadb-backup uses for parallel data file transfers. By default, it is set to 1.

`-p, --password`

Defines the password to use to connect to MariaDB Server.

```
--password=passwd
```

When you run `mariadb-backup`, it connects to MariaDB Server in order to access and back up the databases and tables. Using this option, you can set the password mariadb-backup uses to access the server. To set the user, use the `--user` option.

```
mariadb-backup --backup \
      --user=root \
      --password=root_password
```

`--plugin-dir`

Defines the directory for server plugins.

```
--plugin-dir=PATH
```

Using this option, you can define the path `mariadb-backup` reads for MariaDB Server plugins. It only uses it during the `--prepare` phase to load the encryption plugin. It defaults to the `plugin_dir` server system variable.

```
mariadb-backup --backup \
      --plugin-dir=/var/mysql/lib/plugin
```

`--plugin-load`

The option has been removed.

`-P, --port`

Defines the server port to connect to.

```
--port=#
```

When you run `mariadb-backup`, it connects to MariaDB Server in order to access and back up your databases and tables. Using this option, you can set the port the utility uses to access the server over TCP/IP. To set the host, see the `--host` option. Use `mysql --help` for more details.

```
mariadb-backup --backup \
      --host=192.168.11.1 \
      --port=3306
```

`--prepare`

Prepares an existing backup to restore to the MariaDB Server.

Files that `mariadb-backup` generates during `--backup` operations in the target directory are not ready for use on the Server. Before you can restore the data to MariaDB, you first need to prepare the backup.

In the case of full backups, the files are not point in time consistent, since they were taken at different times. If you try to restore the database without first preparing the data, InnoDB rejects the new data as corrupt. Running mariadb-backup with the `--prepare` command readies the data so you can restore it to MariaDB Server. When working with incremental backups, you need to use the `--prepare` command and the `--incremental-dir` option to update the base backup with the deltas from an incremental backup.

```
mariadb-backup --prepare
```

Once the backup is ready, you can use the `--copy-back` or the `--move-back` options to restore the backup to the server.

`--print-defaults`

Prints the utility argument list, then exits.

Using this argument, MariaDB prints the argument list to stdout and then exits. You may find this useful in debugging to see how the options are set for the utility.

```
mariadb-backup --print-defaults
```

`--print-param`

Prints the MariaDB Server options needed for `copy-back`.

Using this option, `mariadb-backup` prints to stdout the MariaDB Server options that the utility requires to run the `--copy-back` command option.

```
mariadb-backup --print-param
```

`--rollback-xa`

By default, mariadb-backup will not commit or rollback uncommitted XA transactions, and when the backup is restored, any uncommitted XA transactions must be manually committed using `XA COMMIT` or manually rolled back using `XA ROLLBACK`.

MariaDB starting with 10.5

mariadb-backup's `--rollback-xa` option is not present because the server has more robust ways of handling uncommitted XA transactions.

This is an experimental option. Do not use this option in older versions. Older implementation can cause corruption of InnoDB data.

`--rsync`

Defines whether to use rsync.

During normal operation, mariadb-backup transfers local non-InnoDB files using a separate call to `cp` for each file. Using this option, you can optimize this process by performing this transfer with rsync, instead.

```
mariadb-backup --backup --rsync
```

This option is not compatible with the `--stream` option.

Deprecated and has no effect from MariaDB 10.11.8, MariaDB 11.0.6, MariaDB 11.1.5 and MariaDB 11.2.4 as rsync will not work on tables that are in use. See MDEV-32932.

`--safe-slave-backup`

Stops replica SQL threads for backups.

When running `mariadb-backup` on a server that uses replication, you may occasionally encounter locks that block backups. Using this option, it stops replica SQL threads and waits until the `Slave_open_temp_tables` in the `SHOW STATUS` statement is zero. If there are no open temporary tables, the backup runs, otherwise the SQL thread starts and stops until there are no open temporary tables.

```
mariadb-backup --backup \
      --safe-slave-backup \
      --safe-slave-backup-timeout=500
```

The backup fails if the `Slave_open_temp_tables` doesn't reach zero after the timeout period set by the `--safe-slave-backup-timeout` option.

`--safe-slave-backup-timeout`

Defines the timeout for replica backups.

```
--safe-slave-backup-timeout=#
```

When running mariadb-backup on a server that uses replication, you may occasionally encounter locks that block backups. With the `--safe-slave-backup` option, it waits until the `Slave_open_temp_tables` in the `SHOW STATUS` statement reaches zero. Using this option, you set how long it waits. It defaults to 300.

```
mariadb-backup --backup \
      --safe-slave-backup \
      --safe-slave-backup-timeout=500
```

`--secure-auth`

Refuses client connections to servers using the older protocol.

Using this option, you can set it explicitly to refuse client connections to the server when using the older protocol, from before 4.1.1. This feature is enabled by default. Use the `--skip-secure-auth` option to disable it.

```
mariadb-backup --backup --secure-auth
```

`--skip-innodb-adaptive-hash-index`

Disables InnoDB Adaptive Hash Index.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option you can explicitly disable the InnoDB Adaptive Hash Index. This feature is enabled by default for mariadb-backup. If you want to explicitly enable it, use `--innodb-adaptive-hash-index`.

```
mariadb-backup --backup \
      --skip-innodb-adaptive-hash-index
```

`--skip-innodb-doublewrite`

Disables doublewrites for InnoDB tables.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. When doublewrites are enabled, InnoDB improves fault tolerance with a doublewrite buffer. By default this feature is turned on. Using this option you can disable it for mariadb-backup. To explicitly enable doublewrites, use the `--innodb-doublewrite` option.

```
mariadb-backup --backup \
     --skip-innodb-doublewrite
```

`--skip-innodb-log-checksums`

Defines whether to exclude checksums in the InnoDB logs.

`mariadb-backup` initializes its own embedded instance of InnoDB using the same configuration as defined in the configuration file. Using this option, you can set mariadb-backup to exclude checksums in the InnoDB logs. The feature is enabled by default. To explicitly enable it, use the `--innodb-log-checksums` option.

`--skip-secure-auth`

Refuses client connections to servers using the older protocol.

Using this option, you can set it accept client connections to the server when using the older protocol, from before 4.1.1. By default, it refuses these connections. Use the `--secure-auth` option to explicitly enable it.

```
mariadb-backup --backup --skip-secure-auth
```

`--slave-info`

Prints the binary log position and the name of the primary server.

If the server is a replica, then this option causes `mariadb-backup` to print the hostname of the replica's replication primary and the binary log file and position of the replica's SQL thread to `stdout`.

This option also causes `mariadb-backup` to record this information as a `CHANGE MASTER` statement that can be used to set up a new server as a replica of the original server's primary after the backup has been restored. This information are written to the `xtrabackup_slave_info` file.

`mariadb-backup` does **not** check if GTIDs are being used in replication. It takes a shortcut and assumes that if the `gtid_slave_pos` system variable is non-empty, then it writes the `CHANGE MASTER` statement with the `MASTER_USE_GTID` option set to `slave_pos`. Otherwise, it writes the `CHANGE MASTER` statement with the `MASTER_LOG_FILE` and `MASTER_LOG_POS` options using the primary's binary log file and position. See MDEV-19264 for more information.

```
mariadb-backup --slave-info
```

`-S, --socket`

Defines the socket for connecting to local database.

```
--socket=name
```

Using this option, you can define the UNIX domain socket you want to use when connecting to a local database server. The option accepts a string argument. For more information, see the `mysql --help` command.

```
mariadb-backup --backup \
      --socket=/var/mysql/mysql.sock
```

`--ssl`

Enables TLS. By using this option, you can explicitly configure `mariadb-backup` to encrypt its connection with TLS when communicating with the server. You may find this useful when performing backups in environments where security is extra important or when operating over an insecure network.

TLS is also enabled even without setting this option when certain other TLS options are set. For example, see the descriptions of the following options:

- --ssl-ca
- --ssl-capath
- --ssl-cert
- --ssl-cipher
- --ssl-key

`--ssl-ca`

Defines a path to a PEM file that should contain one or more X509 certificates for trusted Certificate Authorities (CAs) to use for TLS. This option requires that you use the absolute path, not a relative path. For example:

```
--ssl-ca=/etc/my.cnf.d/certificates/ca.pem
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem
```

See Secure Connections Overview: Certificate Authorities (CAs) for more information.

This option implies the `--ssl` option.

`--ssl-capath`

Defines a path to a directory that contains one or more PEM files that should each contain one X509 certificate for a trusted Certificate Authority (CA) to use for TLS. This option requires that you use the absolute path, not a relative path. For example:

```
--ssl-capath=/etc/my.cnf.d/certificates/ca/
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem \
   --ssl-capath=/etc/my.cnf.d/certificates/ca/
```

The directory specified by this option needs to be run through the openssl rehash command.

See Secure Connections Overview: Certificate Authorities (CAs) for more information

This option implies the `--ssl` option.

`--ssl-cert`

Defines a path to the X509 certificate file to use for TLS. This option requires that you use the absolute path, not a relative path. For example:

```
--ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem
```

This option implies the `--ssl` option.

`--ssl-cipher`

Defines the list of permitted ciphers or cipher suites to use for TLS. For example:

```
--ssl-cipher=name
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem \
   --ssl-cipher=TLSv1.2
```

To determine if the server restricts clients to specific ciphers, check the ssl_cipher system variable.

This option implies the `--ssl` option.

`--ssl-crl`

Defines a path to a PEM file that should contain one or more revoked X509 certificates to use for TLS. This option requires that you use the absolute path, not a relative path. For example:

```
--ssl-crl=/etc/my.cnf.d/certificates/crl.pem
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem \
   --ssl-crl=/etc/my.cnf.d/certificates/crl.pem
```

See Secure Connections Overview: Certificate Revocation Lists (CRLs) for more information.

This option is only supported if `mariadb-backup` was built with OpenSSL. If `mariadb-backup` was built with yaSSL, then this option is not supported. See TLS and Cryptography Libraries Used by MariaDB for more information about which libraries are used on which platforms.

`--ssl-crlpath`

Defines a path to a directory that contains one or more PEM files that should each contain one revoked X509 certificate to use for TLS. This option requires that you use the absolute path, not a relative path. For example:

```
--ssl-crlpath=/etc/my.cnf.d/certificates/crl/
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem \
   --ssl-crlpath=/etc/my.cnf.d/certificates/crl/
```

The directory specified by this option needs to be run through the openssl rehash command.

See Secure Connections Overview: Certificate Revocation Lists (CRLs) for more information.

This option is only supported if mariadb-backup was built with OpenSSL. If `mariadb-backup` was built with yaSSL, then this option is not supported. See TLS and Cryptography Libraries Used by MariaDB for more information about which libraries are used on which platforms.

`--ssl-key`

Defines a path to a private key file to use for TLS. This option requires that you use the absolute path, not a relative path. For example:

```
--ssl-key=/etc/my.cnf.d/certificates/client-key.pem
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem
```

This option implies the `--ssl` option.

`--ssl-verify-server-cert`

Enables server certificate verification. This option is disabled by default.

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem \
   --ssl-verify-server-cert
```

`--stream`

Streams backup files to stdout.

```
--stream=xbstream
```

Using this command option, you can set `mariadb-backup` to stream the backup files to `stdout` in the given format. Currently, the supported format is `xbstream`.

```
mariadb-backup --stream=xbstream > backup.xb
```

To extract all files from the xbstream archive into a directory use the `mbstream` utility

```
mbstream  -x < backup.xb
```

If a backup is streamed, then `mariadb-backup` records the format in the `xtrabackup_info` file.

`--tables`

Defines the tables you want to include in the backup.

```
--tables=REGEX
```

Using this option, you can define what tables you want `mariadb-backup` to back up from the database. The table values are defined using Regular Expressions (regex[4]). To define the tables you want to exclude from the backup, see the `--tables-exclude` option.

```
mariadb-backup --backup \
     --databases=example \
     --tables=nodes_* \
     --tables-exclude=nodes_tmp
```

In the example, *`nodes_*`* matches tables named *`nodes`*, *`nodes_`*, *`nodes__`*, and so forth, because `*` means *zero or more occurrences of the previous character* (`_`).

If instead you want to back up all tables whose names start with *`nodes`*, the regular expression is `^nodes.`, and to exclude tables starting with *`nodes_tmp`*, the expression is *`^nodes_tmp.`*. (Notice the trailing period (`.`); it means *zero or more occurrences of characters following* *`nodes`*.) The command looks like this:

```
mariadb-backup --backup \
     --databases=example \
     --tables=^nodes. \
     --tables-exclude=^nodes_tmp.
```

In that example, some of the tables included via the `--tables` option are excluded by `--tables-excludes`. That works because `--tables-exclude` takes precedence over `--tables`.

You can specify multiple table name regex[5] patterns as a comma-separated list, for both the `--tables` and the `--tables-exclude` options.

The following command backs up all tables in the *`test1`* and *`test2`* databases, except the *`exclude_table`* table in the *`test2`* database, and stores the backup files under */`path/to/backups/`*:

```
mariadb-backup --backup \
     --tables=test1[.].*,test2[.].* \
     --tables-exclude=^test2[.]exclude_table
     --target-dir=/path/to/backups/
```

Warning:

The `--databases` and `--databases-exclude` options, if used, take precedence over `--tables` and `--tables-exclude`. That is, they can filter out tables, which are then not “visible” to the latter mentioned options.

If a backup is a partial backup, `mariadb-backup` records that detail in the `xtrabackup_info` file.

`--tables-exclude`

Defines the tables you want to exclude from the backup.

```
--tables-exclude=REGEX
```

Using this option, you can define what tables you want `mariadb-backup` to exclude from the backup. The table values are defined using Regular Expressions. To define the tables you want to include from the backup, see the `--tables` option.

> **Note:**
>
> See the `--tables` option for examples and hints regarding regular expressions.

If a backup is a partial backup, `mariadb-backup` records that detail in the `xtrabackup_info` file.

`--tables-file`

Defines path to file with tables for backups.

```
--tables-file=/path/to/file
```

Using this option, you can set a path to a file listing the tables you want to back up. `mariadb-backup` iterates over each line in the file. The format is `database.table`.

```
mariadb-backup --backup \
     --databases=example \
     --tables-file=/etc/mysql/backup-file
```

If a backup is a partial backup, then mariadb-backup will record that detail in the `xtrabackup_info` file.

`--target-dir`

Defines the destination directory.

```
--target-dir=/path/to/target
```

Using this option you can define the destination directory for the backup. `mariadb-backup` writes all backup files to this directory. mariadb-backup will create the directory, if it does not exist (but it does not create the full path recursively, i.e. at least parent directory if the `--target-dir` must exist.

```
mariadb-backup --backup \
       --target-dir=/data/backups
```

`--throttle`

Defines the limit for I/O operations per second in IOS values.

```
--throttle=#
```

Using this option, you can set a limit on the I/O operations mariadb-backup performs per second in IOS values. It is only used during the `--backup` option.

`--tls-version`

This option accepts a comma-separated list of TLS protocol versions. A TLS protocol version is only enabled if it is present in this list. All other TLS protocol versions will not be permitted. For example:

```
--tls-version="TLSv1.2,TLSv1.3"
```

This option is usually used with other TLS options. For example:

```
mariadb-backup --backup \
   --ssl-cert=/etc/my.cnf.d/certificates/client-cert.pem \
   --ssl-key=/etc/my.cnf.d/certificates/client-key.pem \
   --ssl-ca=/etc/my.cnf.d/certificates/ca.pem \
   --tls-version="TLSv1.2,TLSv1.3"
```

See Secure Connections Overview: TLS Protocol Versions for more information.

`-t, --tmpdir`

Defines path for temporary files.

```
--tmpdir=/path/tmp[;/path/tmp...]
```

Using this option, you can define the path to a directory `mariadb-backup` uses in writing temporary files. If you want to use more than one, separate the values by a semicolon (that is, `;`). When passing multiple temporary directories, it cycles through them using round-robin.

```
mariadb-backup --backup \
     --tmpdir=/data/tmp;/tmp
```

`--use-memory`

Defines the buffer pool size that is used during the prepare stage.

```
--use-memory=124M
```

Using this option, you can define the buffer pool size for `mariadb-backup`. Use it instead of `buffer_pool_size`.

```
mariadb-backup --prepare \
      --use-memory=124M
```

`--user`

Defines the username for connecting to the MariaDB Server.

```
--user=name
-u name
```

When `mariadb-backup` runs, it connects to the specified MariaDB Server to get its backups. Using this option, you can define the database user used for authentication. Starting from MariaDB 10.6.17, MariaDB 10.11.7, MariaDB 11.0.5, MariaDB 11.1.4, MariaDB 11.2.3, MariaDB 11.3.2, MariaDB 11.4.1, if the `--user` option is omitted, the user name is detected from the OS.

```
mariadb-backup --backup \
      --user=root \
      --password=root_passwd
```

`--verbose`

Displays verbose output.

```
mariadb-backup --verbose
```

`--version`

Prints the `mariadb-backup` version information to `stdout`.

```
mariadb-backup --version
```

This page is licensed: CC BY-SA / Gnu FDL

Full Backup and Restore (mariadb-backup)

> **Note:**
>
> mariadb-backup was previously called mariabackup.

When using mariadb-backup, you have the option of performing a full or an incremental backup. Full backups create a complete backup of the database server in an empty directory while incremental backups update a previous backup with whatever changes to the data have occurred since the backup. This page documents how to perform full backups.

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

Backing up the Database Server

In order to back up the database, you need to run mariadb-backup with the `--backup` option to tell it to perform a backup and with the `--target-dir` option to tell it where to place the backup files. When taking a full backup, the target directory must be empty or it must not exist.

To take a backup, run the following command:

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

The time the backup takes depends on the size of the databases or tables you're backing up. You can cancel the backup if you need to, as the backup process does not modify the database.

`mariadb-backup` writes the backup files the target directory. If the target directory doesn't exist, it creates it. If the target directory exists and contains files, it raises an error and aborts.

Here is an example backup directory:

```
$ ls /var/mariadb/backup/

aria_log.0000001  mysql                    xtrabackup_checkpoints
aria_log_control  performance_schema       xtrabackup_info
backup-my.cnf     test                     xtrabackup_logfile
ibdata1           xtrabackup_binlog_info
```

Using the Backup History Feature

You can optionally use the `--history` option to record metadata about your full backup in the database. This creates a centralized log and allows future incremental backups to reference this full backup by name instead of by directory path.

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword \
   --history=full_backup_weekly
```

- Privileges: The backup user requires `INSERT`, `CREATE`, and `ALTER` privileges on the history table (`mysql.mariadb_backup_history` in MariaDB 10.11+, or `PERCONA_SCHEMA.xtrabackup_history` in older versions).
- Failure Case: If the user lacks privileges, the backup will complete the file copy process but will fail at the final step with an `INSERT command denied` error.

Preparing the Backup for Restoration

The data files that `mariadb-backup` creates in the target directory are not point-in-time consistent, given that the data files are copied at different times during the backup operation. If you try to restore from these files, InnoDB notices the inconsistencies and crashes to protect you from corruption

Before you can restore from a backup, you first need to **prepare** it to make the data files consistent. You can do so with the `--prepare` option.

```
$ mariadb-backup --prepare \
   --target-dir=/var/mariadb/backup/
```

Backup Preparation Steps

1. Run `mariadb-backup --backup`. You must use a version of `mariadb-backup` that is compatible with the server version you are planning to upgrade from. For instance, when upgrading from MariaDB 10.4 to 10.5, you must use the 10.4 version of `mariadb-backup`, Another example: When upgrading from MariaDB 10.6 to 10.11, you must use the 10.6 version of `mariadb-backup`.
2. Run `mariadb-backup --prepare`, again using a compatible version of `mariadb-backup`, as described in the previous step.

Restoring the Backup

Once the backup is complete and you have prepared the backup for restoration (previous step), you can restore the backup using either the `--copy-back` or the `--move-back` options. The `--copy-back` option allows you to keep the original backup files. The `--move-back` option actually moves the backup files to the datadir, so the original backup files are lost.

- First, stop the MariaDB Server process.
- Then, ensure that `datadir` is empty.
- Then, run `mariadb-backup` with one of the options mentioned above:

```
$ mariadb-backup --copy-back \
   --target-dir=/var/mariadb/backup/
```

- Then, you may need to fix the file permissions.

When `mariadb-backup` restores a database, it preserves the file and directory privileges of the backup. However, it writes the files to disk as the user and group restoring the database. As such, after restoring a backup, you may need to adjust the owner of the data directory to match the user and group for the MariaDB Server, typically `mysql` for both. For example, to recursively change ownership of the files to the `mysql` user and group, you could execute:

```
$ chown -R mysql:mysql /var/lib/mysql/
```

- Finally, start the MariaDB Server process.

Restoring with Other Tools

Once a full backup is prepared, it is a fully functional MariaDB data directory. Therefore, as long as the MariaDB Server process is stopped on the target server, you can technically restore the backup using any file copying tool, such as `cp` or `rsync`. For example, you could also execute the following to restore the backup:

```
$ rsync -avrP /var/mariadb/backup /var/lib/mysql/
$ chown -R mysql:mysql /var/lib/mysql/
```

Incremental Backup and Restore (mariadb-backup)

> **Note:**
>
> mariadb-backup was previously called mariabackup.

When using `mariadb-backup`, you have the option of performing a full or incremental backup. Full backups create a complete copy in an empty directory while incremental backups update a previous backup with new data. This page documents incremental backups.

InnoDB pages contain log sequence numbers, or LSN's. Whenever you modify a row on any InnoDB table on the database, the storage engine increments this number. When performing an incremental backup, `mariadb-backup` checks the most recent LSN for the backup against the LSN's contained in the database. It then updates any of the backup files that have fallen behind.

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

Backing up the Database Server

In order to take an incremental backup, you first need to take a full backup. In order to back up the database, you need to run `mariadb-backup` with the `--backup` option to tell it to perform a backup and with the `--target-dir` option to tell it where to place the backup files. When taking a full backup, the target directory must be empty or it must not exist.

To take a backup, run the following command:

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

This backs up all databases into the target directory `/var/mariadb/backup`. If you look in that directory at the `mariadb_backup_checkpoints` file, you can see the LSN data provided by InnoDB.

For example:

```
backup_type = full-backuped
from_lsn = 0
to_lsn = 1635102
last_lsn = 1635102
recover_binlog_info = 0
```

Backing up the Incremental Changes

Once you have created a full backup on your system, you can also back up the incremental changes as often as you would like.

In order to perform an incremental backup, you need to run `mariadb-backup` with the `--backup` option to tell it to perform a backup and with the `--target-dir` option to tell it where to place the incremental changes. The target directory must be empty. You also need to run it with the `--incremental-basedir` option to tell it the path to the full backup taken above. For example:

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/inc1/ \
   --incremental-basedir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

This command creates a series of delta files that store the incremental changes in `/var/mariadb/inc1`. You can find a similar `mariadb_backup_checkpoints` file in this directory, with the updated LSN values.

> **Note:**
>
> In MariaDB 11.0 and earlier, this file is named `xtrabackup_checkpoints`. The new name is recognized as a fallback for backups taken with older versions.

For example:

```
backup_type = incremental
from_lsn = 1635102
to_lsn = 1635114
last_lsn = 1635114
recover_binlog_info = 0
```

To perform additional incremental backups, you can then use the target directory of the previous incremental backup as the incremental base directory of the next incremental backup. For example:

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/inc2/ \
   --incremental-basedir=/var/mariadb/inc1/ \
   --user=mariadb-backup --password=mypassword
```

Using the Backup History Table

Alternatively, you can use the backup history table to manage your backup chain. This allows you to reference the previous backup by a logical name instead of a directory path.

1. **Create the Base Backup:** Take a full backup using the `--history` option.

   ```
   mariadb-backup --backup --target-dir=/full \
     --history=full_backup_1
   ```

2. **Create the Incremental Backup:** Use `--incremental-history-name` to specify the base backup's name. It is recommended to use `--history` again to record this new incremental backup.

   ```
   mariadb-backup --backup --target-dir=/inc1 \
     --incremental-history-name=full_backup_1 \
     --history=inc_backup_1
   ```

Note:

Privileges

Requires `SELECT` on the history table to find the base backup, and `INSERT` to record the new one.

Tip:

You can also use `--incremental-history-uuid` if you prefer to reference the unique ID generated by `mariadb-backup`.

Combining With `--stream` Output

When using `--stream`, for instance for compression or encryption using external tools, the `mariadb_backup_checkpoints` file containing the information where to continue from on the next incremental backup will also be part of the compressed/encrypted backup file, and so not directly accessible by default.

A directory containing an extra copy of the file can be created using the `--extra-lsndir=..` option though, and this directory can then be passed to the next incremental backup `--incremental-basedir=...`, for example:

```
# initial full backup
$ mariadb-backup --backup --stream=mbstream \
  --user=mariadb-backup --password=mypassword \
  --extra-lsndir=backup_base | gzip > backup_base.gz

# incremental backup
$ mariadb-backup --backup --stream=mbstream \
  --incremental-basedir=backup_base \
  --user=mariadb-backup --password=mypassword \
  --extra-lsndir=backup_inc1 | gzip > backup-inc1.gz
```

Preparing the Backup

Following the above steps, you have three backups in `/var/mariadb`: The first is a full backup, the others are increments on this first backup. In order to restore a backup to the database, you first need to apply the incremental backups to the base full backup. This is done using the `--prepare` command option.

Perform the following process:

First, prepare the base backup:

```
$ mariadb-backup --prepare \
   --target-dir=/var/mariadb/backup
```

Running this command brings the base full backup, that is, `/var/mariadb/backup`, into sync with the changes contained in the InnoDB redo log collected while the backup was taken.

Then, apply the incremental changes to the base full backup:

```
$ mariadb-backup --prepare \
   --target-dir=/var/mariadb/backup \
   --incremental-dir=/var/mariadb/inc1
```

Running this command brings the base full backup, that is, `/var/mariadb/backup`, into sync with the changes contained in the first incremental backup.

For each remaining incremental backup, repeat the last step to bring the base full backup into sync with the changes contained in that incremental backup.

Restoring the Backup

Once you've applied all incremental backups to the base, you can restore the backup using either the `--copy-back` or the `--move-back` options. The `--copy-back` option allows you to keep the original backup files. The `--move-back` option actually moves the backup files to the `datadir`, so the original backup files are lost.

- First, stop the MariaDB Server process.
- Then, ensure that the `datadir` is empty.
- Then, run `mariadb-backup` with one of the options mentioned above:

```
$ mariadb-backup --copy-back \
   --target-dir=/var/mariadb/backup/
```

- Then, you may need to fix the file permissions.

When `mariadb-backup` restores a database, it preserves the file and directory privileges of the backup. However, it writes the files to disk as the user and group restoring the database. As such, after restoring a backup, you may need to adjust the owner of the data directory to match the user and group for the MariaDB Server, typically `mysql` for both. For example, to recursively change ownership of the files to the `mysql` user and group, you could execute:

```
$ chown -R mysql:mysql /var/lib/mysql/
```

- Finally, start the MariaDB Server process.

Partial Backup and Restore (mariadb-backup)

> **Note:**
>
> mariadb-backup was previously called mariabackup.

When using `mariadb-backup`, you have the option of performing partial backups. Partial backups allow you to choose which databases or tables to backup, as long as the table or partition involved is in an InnoDB file-per-table tablespace.This page documents how to perform partial backups.

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

Backing up the Database Server

Just like with full backups, in order to back up the database, you need to run mariadb-backup with the `--backup` option to tell it to perform a backup and with the `--target-dir` option to tell it where to place the backup files. The target directory must be empty or not exist.

For a partial backup, there are a few other arguments that you can provide as well:

- To tell it which databases to backup, you can provide the `--databases` option.
- To tell it which databases to exclude from the backup, you can provide the `--databases-exclude` option.
- To tell it to check a file for the databases to backup, you can provide the `--databases-file` option.
- To tell it which tables to back up, you can use the `--tables` option.
- To tell it which tables to exclude from the backup, you can provide the `--tables-exclude` option.
- To tell it to check a file for specific tables to backup, you can provide the `--tables-file` option.

The non-file partial backup options support regex in the database and table names.

For example, to take a backup of any database that starts with the string `app1_` and any table in those databases that start with the string `tab_`, run the following command:

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/backup/ \
   --databases='app1 app2' --tables='tab_[0-9]+' \
   --user=mariadb-backup --password=mypassword
```

Using –history with Partial Backups

You can use the `--history` option with a partial backup to log the operation in the history table for auditing purposes.

```
mariadb-backup --backup --databases="db1" \
  --target-dir=/backup --history=partial_db1
```

Warning:

You cannot use a partial backup as the base for an incremental backup history chain. The `--incremental-history-name` option is incompatible with partial backups because restoring partial incrementals requires specific preparation steps (`--export`) that the history feature does not automate.

Note:

`mariadb-backup` cannot back up a subset of partitions from a partitioned table. Backing up a partitioned table is an all-or-nothing selection. See MDEV-17132 about that. If you need to backup a subset of partitions, one possibility is that instead of using `mariadb-backup` , you can export the file-per-table tablespaces of the partitions.

The time the backup takes depends on the size of the databases or tables you're backing up. You can cancel the backup if you need to, as the backup process does not modify the database.

`mariadb-backup` writes the backup files to the target directory. If the target directory doesn't exist, then it creates it. If the target directory exists and contains files, then it raises an error and aborts.

Preparing the Backup

Just like with full backups, the data files that `mariadb-backup` creates in the target directory are not point-in-time consistent, given that the data files are copied at different times during the backup operation. If you try to restore from these files, InnoDB notices the inconsistencies and crashes to protect you from corruption. In fact, for partial backups, the backup is not even a completely functional MariaDB data directory, so InnoDB would raise more errors than it would for full backups. This point will also be very important to keep in mind during the restore process.

Before you can restore from a backup, you first need to **prepare** it to make the data files consistent. You can do so with the `--prepare` command option.

Partial backups rely on InnoDB's transportable tablespaces. For MariaDB to import tablespaces like these, InnoDB looks for a file with a `.cfg` extension. For `mariadb-backup` to create these files, you also need to add the `--export` option during the prepare step.

For example, you might execute the following command:

```
$ mariadb-backup --prepare --export \
   --target-dir=/var/mariadb/backup/
```

If this operation completes without error, then the backup is ready to be restored.

`mariadb-backup` did not support the `--export` option. See MDEV-13466 about that. This means that `mariadb-backup` could not create `.cfg` files for InnoDB file-per-table tablespaces during the `--prepare` stage. You can still import file-per-table tablespaces without the `.cfg` files in many cases, so it may still be possible in those versions to restore partial backups or to restore individual tables and partitions with just the `.ibd` files. If you have a full backup and you need to create `.cfg` files for InnoDB file-per-table tablespaces, then you can do so by preparing the backup as usual without the `--export` option, and then restoring the backup, and then starting the server. At that point, you can use the server's built-in features to copy the transportable tablespaces.

Restoring the Backup

The restore process for partial backups is quite different than the process for full backups. A partial backup is not a completely functional data directory. The data dictionary in the InnoDB system tablespace will still contain entries for the databases and tables that were not included in the backup.

Rather than using the `--copy-back` or the `--move-back`, each individual InnoDB file-per-table tablespace file will have to be manually imported into the target server. The process that is used to import the file will depend on whether partitioning is involved.

Restoring Individual Non-Partitioned Tables

To restore individual non-partitioned tables from a backup, find the `.ibd` and `.cfg` files for the table in the backup, and then import them using the Importing Transportable Tablespaces for Non-partitioned Tables process.

Restoring Individual Partitions and Partitioned Tables

To restore individual partitions or partitioned tables from a backup, find the `.ibd` and `.cfg` files for the partitions in the backup, and then import them using the Importing Transportable Tablespaces for Partitioned Tables process.

Restoring Individual Tables with Full-Text Indexes

When restoring a table with a full-text search (FTS) index, InnoDB may throw a schema mismatch error.

In this case, to restore the table, it is recommended to:

- Remove the corresponding `.cfg` file.
- Restore data to a table without any secondary indexes including FTS.
- Add the necessary secondary indexes to the restored table.

For example, to restore table `t1` with FTS index from database `db1`:

1. In the MariaDB Command-Line Client, drop the table you are going to restore:

```
DROP TABLE IF EXISTS db1.t1;
```

2. Create an empty table for the data being restored:

```
CREATE TABLE db1.t1(f1 CHAR(10)) ENGINE=INNODB;
```

3. Modify the table to discard the tablespace:

```
ALTER TABLE db1.t1 DISCARD TABLESPACE;
```

4. In the operating system shell, copy the table files from the backup to the data directory of the corresponding database:

```
$ sudo cp /data/backups/part/db1/t1.* /var/lib/mysql/db1
```

5. Remove the `.cfg` file from the data directory:

```
$ sudo rm /var/lib/mysql/db1/t1.cfg
```

6. Change the owner of the newly copied files to the system user running MariaDB Server:

```
$ sudo chown mysql:mysql /var/lib/mysql/db1/t1.*
```

7. In the MariaDB Command-Line Client, import the copied tablespace:

```
ALTER TABLE db1.t1 IMPORT TABLESPACE;
```

8. Verify that the data has been successfully restored:

```
SELECT * FROM db1.t1;
```

9. Add the necessary secondary indexes:

```
ALTER TABLE db1.t1 FORCE, ADD FULLTEXT INDEX f_idx(f1);
```

10. The table is now fully restored:

```
SHOW CREATE TABLE db1.t1\G
*************************** 1. row ***************************
       Table: t1
Create Table: CREATE TABLE `t1` (
  `f1` char(10) DEFAULT NULL,
  FULLTEXT KEY `f_idx` (`f1`)
) ENGINE=InnoDB DEFAULT CHARSET=utf8mb4 COLLATE=utf8mb4_general_ci
```

This page is licensed: CC BY-SA / Gnu FDL

Point-In-Time Recovery (PITR, mariadb-backup)

Recovering from a backup can restore the data directory at a specific point in time, but it does not restore the binary log. In a point-in-time recovery, start by restoring the data directory from a full or incremental backup, then use the mysqlbinlog utility to restore the binary log data to a specific point in time.

> **Warning:**
>
> Run the following commands as root unless indicated otherwise.

> **Step 1**
>
> **Find the binary log position to restore to.**
>
> When MariaDB Backup runs on a MariaDB Server with binary logs enabled (which is a prerequisite for PITR), it stores binary log information in the `mariadb_backup_binlog_info` (or `xtrabackup_binlog_info` in older releases) file. Consult this file to find the name of the binary log position to use. In the following example, the log position is 321:

```
cat /data/backups/full/mariadb_backup_binlog_info

mariadb-node4.00001     321
```

Step 2

Configure a new data directory.

Update the configuration file (for instance, `my.cnf`) to use a new data directory.

```
[mysqld]
datadir=/var/lib/mysql_new
```

Step 3

Restore the backup.

Restore from the backup as explained here.

Step 4

Start the database server.

Start MariaDB Server.

```
systemctl start mariadb
```

Step 5

Create a script using mysqlbinlog.

Use the mysqlbinlog utility to create an SQL script, using the binary log file in the *old* data directory, the start position in the `xtrabackup_binlog_info` file, and the date and time you want to restore to. Issue the following command *as a regular user*:

```
$ mysqlbinlog --start-position=321 \
      --stop-datetime="2019-06-28 12:00:00" \
      /var/lib/mysql/mariadb-node4.00001 \
      > mariadb-binlog.sql
```

Step 6

Run the script.

In the *new* data directory, run the script created in the previous step:

```
$ mariadb < mariadb-binlog.sql
```

See Also

- Point-In-Time Recovery (InnoDB log archiving) — an alternative PITR procedure that replays archived InnoDB write-ahead logs instead of binary logs. Available from MariaDB 13.0.

Warning:

`mariadb-backup` does not support the `innodb_log_archive =ON` log format and fails when the server is running with `innodb_log_archive=ON`. Use the InnoDB log archiving PITR procedure instead in that configuration.

Restoring Individual Databases From a Full Backup (mariadb-backup)

Individual Database Restores with mariadb-backup from Full Backup

> **Note:**
>
> mariadb-backup was previously called mariabackup.

This method is to solve a flaw with mariadb-backup; it cannot do single database restores from a full backup easily. There is a blog post that details a way to do this, but it's a manual process which is fine for a few tables but if you have hundreds or even thousands of tables then it would be impossible to do quickly.

We can't just move the data files to the datadir as the tables are not registered in the engines, so the database will error. Currently, the only effective method is to a do full restore in a test database and then dump the database that requires restoring or running a partial backup.

This has only been tested with InnoDB. Also, if you have stored procedures or triggers then these will need to be deleted and recreated.

Some of the issues that this method overcomes:

- Tables not registered in the InnoDB engine so will error when you try to select from a table if you move the data files into the datadir
- Tables with foreign keys need to be created without keys, otherwise it will error when you discard the tablespace

Single Node

Below is the process to perform a single database restore.

Firstly, we will need the table structure from a mariadb-dump backup with the –no-data option. I recommend this is done at least once per day or every six hours via a cronjob. As it is just the structure, it are very fast.

```
mariadb-dump -u root -p --all-databases --no-data > nodata.sql
```

Using SED to return only the table structure we require, then use vim or another text editor to make sure nothing is left.

```
sed -n '/Current Database: `DATABASENAME`/, /Current Database:/p' nodata.sql > trimednodata.sql
vim trimednodata.sql
```

Prepare the backup with any incremental-backup-and-restores that you have, and then run the following on the full backup folder using the `--export` option to generate files with .cfg extensions which InnoDB will look for.

```
mariadb-backup --prepare --export --target-dir=/media/backups/fullbackupfolder
```

Once we have done these steps, we can then import the table structure. If you have used the `--all-databases` option, then you will need to either use SED or open it in a text editor and export out tables that you require. You will also need to log in to the database and create the database if the dump file doesn't. Run the following command below:

```
mysql -u root -p schema_name < nodata.sql
```

Once the structure is in the database, we have now registered the tables to the engine. Next, we will run the following statements in the information_schema database, to export statements to import/discard table spaces and drop and create foreign keys which we will use later. (edit the `CONSTRAINT_SCHEMA` and `TABLE_SCHEMA` `WHERE` clause to the database you are restoring. Also, add the following lines after your `SELECT` and before the `FROM` to have MariaDB export the files to the OS)

```
SELECT ...
INTO OUTFILE '/tmp/filename.SQL'
FIELDS TERMINATED BY ','
LINES TERMINATED BY '\n'
FROM ...
```

The following are the statements that we will need later.

```
USE information_schema;
SELECT concat("ALTER TABLE ",table_name," DISCARD TABLESPACE;")  AS discard_tablespace
FROM information_schema.tables
WHERE TABLE_SCHEMA="DATABASENAME";

SELECT concat("ALTER TABLE ",table_name," IMPORT TABLESPACE;") AS import_tablespace
FROM information_schema.tables
WHERE TABLE_SCHEMA="DATABASENAME";

SELECT
CONCAT ("ALTER TABLE ", rc.CONSTRAINT_SCHEMA, ".",rc.TABLE_NAME," DROP FOREIGN KEY ",
rc.CONSTRAINT_NAME,";") AS drop_keys
FROM REFERENTIAL_CONSTRAINTS AS rc
WHERE CONSTRAINT_SCHEMA = 'DATABASENAME';

SELECT
CONCAT ("ALTER TABLE ",
KCU.CONSTRAINT_SCHEMA, ".",
KCU.TABLE_NAME,"
ADD CONSTRAINT ",
KCU.CONSTRAINT_NAME, "
FOREIGN KEY ", "
(`",KCU.COLUMN_NAME,"`)", "
REFERENCES `",REFERENCED_TABLE_NAME,"`
(`",REFERENCED_COLUMN_NAME,"`)" ,"
ON UPDATE " ,(SELECT UPDATE_RULE FROM REFERENTIAL_CONSTRAINTS WHERE CONSTRAINT_NAME = KCU.CONSTRAINT_NAME
AND CONSTRAINT_SCHEMA = KCU.CONSTRAINT_SCHEMA),"
ON DELETE ",(SELECT DELETE_RULE FROM REFERENTIAL_CONSTRAINTS WHERE CONSTRAINT_NAME = KCU.CONSTRAINT_NAME
AND CONSTRAINT_SCHEMA = KCU.CONSTRAINT_SCHEMA),";") AS add_keys
FROM KEY_COLUMN_USAGE AS KCU
WHERE KCU.CONSTRAINT_SCHEMA = 'DATABASENAME'
AND KCU.POSITION_IN_UNIQUE_CONSTRAINT >= 0
AND KCU.CONSTRAINT_NAME NOT LIKE 'PRIMARY';
```

Once we have run those statements, and they have been exported to a Linux directory or copied from a GUI interface.

Run the `ALTER DROP KEYS` statements in the database.

```
ALTER TABLE schemaname.tablename DROP FOREIGN KEY key_name;
...
```

Once completed, run the `DROP TABLE SPACE` statements in the database:

```
ALTER TABLE test DISCARD TABLESPACE;
...
```

Exit out the database and change into the directory of the full backup location. Run the following commands to copy all the `.cfg` and `.ibd` files to the datadir such as `/var/lib/mysql/testdatabase` (change the `datadir` location if needed). Learn more about files that `mariadb-backup` generates with files-created-by-mariadb-backup.

```
cp *.cfg /var/lib/mysql
cp *.ibd /var/lib/mysql
```

After moving the files, it is very important that MySQL is the owner of the files, otherwise it won't have access to them and will error when we import the tablespaces.

```
sudo chown -R mysql:mysql /var/lib/mysql
```

Run the import table spaces statements in the database.

```
ALTER TABLE test IMPORT TABLESPACE;
...
```

Run the add key statements in the database

```
ALTER TABLE schmeaname.tablename ADD CONSTRAINT key_name FOREIGN KEY (`column_name`) REFERENCES
`foreign_table` (`colum_name`) ON UPDATE NO ACTION ON DELETE NO ACTION;
...
```

We have successfully restored a single database. To test that this has worked, we can do a basic check on some tables.

```
USE DATABASE
SELECT * FROM test LIMIT 10;
```

Replica nodes

If you have a primary-replica set up, it would be best to follow the sets above for the primary node and then either take a full mariadb-dump or take a new full mariadb-backup and restore this to the replica. You can find more information about restoring a replica with mariadb-backup in Setting up a Replica with mariadb-backup

After running the below command, copy to the replica and use the `LESS` linux command to grab the change master statement. Remember to follow this process: Stop replica > restore data > run `CHANGE MASTER` statement > start replica again.

```
mariadb-dump -u user -p --single-transaction --master-data=2 > fullbackup.sql
```

Please follow Setting up a Replica with mariadb-backup on restoring a replica with `mariadb-backup`:

```
$ mariadb-backup \
   --slave-info --safe-slave-backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

Galera Cluster

For this process to work with Galera cluster, we first need to understand that some statements are not replicated across Galera nodes. One of which is the `DISCARD` and `IMPORT` for `ALTER TABLES` statements, and these statements will need to be ran on all nodes. We also need to run the OS level steps on each server as seen below.

Run the `ALTER DROP KEYS` statements on ONE NODE as these are replicated.

```
ALTER TABLE schemaname.tablename DROP FOREIGN KEY key_name;
...
```

Once completed, run the `DROP TABLE SPACE` statements on EVERY NODE, as these are not replicated.

```
ALTER TABLE test DISCARD TABLESPACE;
...
```

Exit out the database and change into the directory of the full backup location. Run the following commands to copy all the `.cfg` and `.ibd` files to the datadir such as `/var/lib/mysql/testdatabase` (change the `datadir` location if needed). Learn more about files that `mariadb-backup` generates with files-created-by-mariadb-backup. This step needs to be done on all nodes. You will need to copy the backup files to each node, we can use the same backup on all nodes.

```
cp *.cfg /var/lib/mysql
cp *.ibd /var/lib/mysql
```

After moving the files, it is very important that MySQL is the owner of the files, otherwise it won't have access to them and will error when we import the tablespaces.

```
sudo chown -R mysql:mysql /var/lib/mysql
```

Run the import table spaces statements on EVERY NODE.

```
ALTER TABLE test IMPORT TABLESPACE;
...
```

Run the add key statements on ONE NODE.

```
ALTER TABLE schmeaname.tablename ADD CONSTRAINT key_name FOREIGN KEY (`column_name`) REFERENCES
`foreign_table` (`colum_name`) ON UPDATE NO ACTION ON DELETE NO ACTION;
...
```

Restoring Individual Tables and Partitions (mariadb-backup)

Restoring Individual Tables and Partitions with mariadb-backup

> **Note:**
>
> mariadb-backup was previously called mariabackup.

When using `mariadb-backup`, you don't necessarily need to restore every table and/or partition that was backed up. Even if you're starting from a full backup, it is certainly possible to restore only certain tables and/or partitions from the backup, as long as the table or partition involved is in an InnoDB file-per-table tablespace. This page documents how to restore individual tables and partitions.

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

Preparing the Backup

Before you can restore from a backup, you first need to **prepare** it to make the data files consistent. You can do so with the `--prepare` option.

The ability to restore individual tables and partitions relies on InnoDB's transportable tablespaces. For MariaDB to import tablespaces like these, InnoDB looks for a file with a `.cfg` extension. For mariadb `-backup` to create these files, you also need to add the `--export` option during the prepare step.

For example, you might execute the following command:

```
$ mariadb-backup --prepare --export \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

If this operation completes without error, then the backup is ready to be restored.

Note

`mariadb-backup` did not support the –export option to begin with. See MDEV-13466 about that. In earlier versions of MariaDB, this means that mariadb-backup could not create `.cfg` files for InnoDB file-per-table tablespaces during the `--prepare` stage. You can still import file-per-table tablespaces without the `.cfg` files in many cases, so it may still be possible in those versions to restore partial backups or to restore individual tables and partitions with just the `.ibd` files. If you have a full backup and you need to create `.cfg` files for InnoDB file-per-table tablespaces, then you can do so by preparing the backup as usual without the `--export` option, and then restoring the backup, and then starting the server. At that point, you can use the server's built-in features to copy the transportable tablespaces.

Restoring the Backup

The restore process for restoring individual tables and/or partitions is quite different than the process for full backups.

Rather than using the `--copy-back` or the `--move-back`, each individual InnoDB file-per-table tablespace file will have to be manually imported into the target server. The process that is used to restore the backup will depend on whether partitioning is involved.

Restoring Individual Non-Partitioned Tables

To restore individual non-partitioned tables from a backup, find the `.ibd` and `.cfg` files for the table in the backup, and then import them using the Importing Transportable Tablespaces for Non-partitioned Tables process.

Restoring Individual Partitions and Partitioned Tables

To restore individual partitions or partitioned tables from a backup, find the `.ibd` and `.cfg` files for the partitions in the backup, and then import them using the Importing Transportable Tablespaces for Partitioned Tables process.

Setting up a Replica (mariadb-backup)

Setting up a Replica with mariadb-backup

> **Note:**
>
> The terms *master* and *slave* have historically been used in replication, and MariaDB has begun the process of adding *primary* and *replica* synonyms. The old terms will continue to be used to maintain backward compatibility - see MDEV-18777 to follow progress on this effort.

> **Note:**
>
> mariadb-backup was previously called mariabackup.

This page documents how to set up a replica from a backup.

If you are using MariaDB Galera Cluster, then you may want to try one of the following pages instead:

- Configuring MariaDB Replication between MariaDB Galera Cluster and MariaDB Server
- Configuring MariaDB Replication between Two MariaDB Galera Clusters

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

Back up the Database and Prepare it

The first step is to simply take and prepare a fresh full backup of a database server in the replication topology. If the source database server is the desired replication primary, then we do not need to add any additional options when taking the full backup. For example:

```
$ mariadb-backup --backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

If the source database server is a replica of the desired primary, then we should add the `--slave-info` option, and possibly the `--safe-slave-backup` option. For example:

```
$ mariadb-backup --backup \
   --slave-info --safe-slave-backup \
   --target-dir=/var/mariadb/backup/ \
   --user=mariadb-backup --password=mypassword
```

And then we would prepare the backup as you normally would. For example:

```
$ mariadb-backup --prepare \
   --target-dir=/var/mariadb/backup/
```

Copy the Backup to the New Replica

Once the backup is done and prepared, we can copy it to the new replica. For example:

```
$ rsync -avP /var/mariadb/backup dbserver2:/var/mariadb/backup
```

Restore the Backup on the New Replica

At this point, we can restore the backup to the `datadir`, as you normally would. For example:

```
$ mariadb-backup --copy-back \
   --target-dir=/var/mariadb/backup/
```

And adjusting file permissions, if necessary:

```
$ chown -R mysql:mysql /var/lib/mysql/
```

Create a Replication User on the Primary

Before the new replica can begin replicating from the primary, we need to create a user account on the primary that the replica can use to connect, and we need to grant the user account the `REPLICATION SLAVE` privilege. For example:

```
CREATE USER 'repl'@'dbserver2' IDENTIFIED BY 'password';
GRANT REPLICATION SLAVE ON *.*  TO 'repl'@'dbserver2';
```

Configure the New Replica

Before we start the server on the new replica, we need to configure it. At the very least, we need to ensure that it has a unique server_id value. We also need to make sure other replication settings are what we want them to be, such as the various GTID system variables, if those apply in the specific environment.

Once configuration is done, we can start the MariaDB Server process on the new replica.

Start Replication on the New Replica

At this point, we need to get the replication coordinates of the primary from the original backup directory.

If we took the backup on the primary, then the coordinates are in the `xtrabackup_binlog_info` file. If we took the backup on another replica and if we provided the `--slave-info` option, then the coordinates are in the file `xtrabackup_slave_info` file.

mariadb-backup dumps replication coordinates in two forms: GTID coordinates and binary log file and position coordinates, like the ones you would normally see from `SHOW MASTER STATUS` output. We can choose which set of coordinates we would like to use to set up replication.

For example:

```
mariadb-bin.000096 568 0-1-2
```

Regardless of the coordinates we use, we will have to set up the primary connection using `CHANGE MASTER TO` and then start the replication threads with `START SLAVE`.

GTIDs

If we want to use GTIDs, then we will have to first set `gtid_slave_pos` to the GTID coordinates that we pulled from either the `xtrabackup_binlog_info` file or the `xtrabackup_slave_info` file in the backup directory. For example:

```
$ cat xtrabackup_binlog_info
mariadb-bin.000096 568 0-1-2
```

And then we would set `MASTER_USE_GTID=slave_pos` in the `CHANGE MASTER TO` statement. For example:

```
SET GLOBAL gtid_slave_pos = "0-1-2";
CHANGE MASTER TO
   MASTER_HOST="dbserver1",
   MASTER_PORT=3306,
   MASTER_USER="repl",
   MASTER_PASSWORD="password",
   MASTER_USE_GTID=slave_pos;
START SLAVE;
```

File and Position

If we want to use the binary log file and position coordinates, then we would set `MASTER_LOG_FILE` and `MASTER_LOG_POS` in the `CHANGE MASTER TO` statement to the file and position coordinates that we pulled; either the `xtrabackup_binlog_info` file or the `xtrabackup_slave_info` file in the backup directory, depending on whether the backup was taken from the primary or from a replica of the primary. For example:

```
CHANGE MASTER TO
   MASTER_HOST="dbserver1",
   MASTER_PORT=3306,
   MASTER_USER="repl",
   MASTER_PASSWORD="password",
   MASTER_LOG_FILE='mariadb-bin.000096',
   MASTER_LOG_POS=568;
START SLAVE;
```

Check the Status of the New Replica

We should be done setting up the replica now, so we should check its status with `SHOW SLAVE STATUS`. For example:

```
SHOW SLAVE STATUS\G
```

Files Backed Up by mariadb-backup

> **Note:**
>
> mariadb-backup was previously called mariabackup.

Files Included in Backup

`mariadb-backup` backs up the files listed below.

InnoDB Data Files

mariadb-backup backs up the following InnoDB data files:

- InnoDB system tablespace
- InnoDB file-per-table tablespaces

MyRocks Data Files

> **CURRENT**
>
> `mariadb-backup` will back up tables that use the MyRocks storage engine. This data is located in the directory defined by the rocksdb_datadir system variable. `mariadb-backup` backs this data up by performing a checkpoint using the rocksdb_create_checkpoint system variable.
>
> **< 10.3.8 TO 10.2.16**
>
> `mariadb-backup` will back up tables that use the MyRocks storage engine.

Other Data Files

`mariadb-backup` also backs up files with the following extensions:

- `frm`
- `isl`
- `MYD`
- `MYI`
- `MAD`
- `MAI`

- `MRG`
- `TRG`
- `TRN`
- `ARM`
- `ARZ`
- `CSM`
- `CSV`
- `opt`
- `par`

Files Excluded From Backup

`mariadb-backup` does **not** back up the files listed below.

- InnoDB Temporary Tablespaces
- Binary logs
- Relay logs

This page is licensed: CC BY-SA / Gnu FDL

Files Created by mariadb-backup

> **Note:**
>
> mariadb-backup was previously called mariabackup.

`mariadb-backup` creates the following files:

`backup-my.cnf`

During the backup, any server options relevant to `mariadb-backup` are written to the `backup-my.cnf` option file, so that they can be re-read later during the `--prepare` stage.

`ib_logfile0`

`mariadb-backup` creates an empty InnoDB redo log file called `ib_logfile0` as part of the `--prepare` stage. This file has 3 roles:

1. In the source server, `ib_logfile0` is the first (and possibly the only) InnoDB redo log file.
2. In the non-prepared backup, `ib_logfile0` contains all of the InnoDB redo log copied during the backup.
3. During the `--prepare` stage, `ib_logfile0` is initialized as an empty InnoDB redo log file. That way, if the backup is manually restored, any pre-existing InnoDB redo log files get overwritten by the empty one. This helps to prevent certain kinds of known issues.

> **CURRENT**
>
> #### `mariadb_backup_binlog_info`
>
> This file stores the binary log file name and position that corresponds to the backup.
>
> This file also stores the value of the gtid_current_pos system variable that correspond to the backup, like this:
>
> ```
> mariadb-bin.000096 568 0-1-2
> ```

The values in this file are only guaranteed to be consistent with the backup if the –no-lock option was **not** provided when the backup was taken.

< 11.1

`xtrabackup_binlog_info`

This file stores the binary log file name and position that corresponds to the backup.

This file also stores the value of the gtid_current_pos system variable that correspond to the backup, like this:

```
mariadb-bin.000096 568 0-1-2
```

The values in this file are only guaranteed to be consistent with the backup if the –no-lock option was **not** provided when the backup was taken.

CURRENT

`mariadb_backup_binlog_pos_innodb`

This file is created by `mariadb-backup` to provide the binary log file name and position when the `--no-lock` option is used. It can be used instead of the `xtrabackup_binlog_info` file to obtain transactionally consistent binlog coordinates from the backup of a master server with the `--no-lock` option to minimize the impact on a running server.

Whenever a transaction is committed inside InnoDB when the binary log is enabled, the corresponding binlog coordinates are written to the InnoDB redo log along with the transaction commit. This allows one to restore the binlog coordinates corresponding to the last commit done by InnoDB along with a backup.

The limitation of using `xtrabackup_binlog_pos_innodb` with the `--no-lock` option is that no DDL or modification of non-transactional tables should be done during the backup. If the last event in the binlog is a DDL/non-transactional update, the coordinates in the file `xtrabackup_binlog_pos_innodb` are too old. But as long as only InnoDB updates are done during the backup, the coordinates are correct.

< 11.1

`xtrabackup_binlog_pos_innodb`

This file is created by `mariadb-backup` to provide the binary log file name and position when the `--no-lock` option is used. It can be used instead of the `xtrabackup_binlog_info` file to obtain transactionally consistent binlog coordinates from the backup of a master server with the `--no-lock` option to minimize the impact on a running server.

Whenever a transaction is committed inside InnoDB when the binary log is enabled, the corresponding binlog coordinates are written to the InnoDB redo log along with the transaction commit. This allows one to restore the binlog coordinates corresponding to the last commit done by InnoDB along with a backup.

The limitation of using `xtrabackup_binlog_pos_innodb` with the `--no-lock` option is that no DDL or modification of non-transactional tables should be done during the backup. If the last event in the binlog is a DDL/non-transactional update, the coordinates in the file `xtrabackup_binlog_pos_innodb` are too old. But as long as only InnoDB updates are done during the backup, the coordinates are correct.

CURRENT

`mariadb_backup_checkpoints`

The `xtrabackup_checkpoints` file contains metadata about the backup.

For example:

```
backup_type = full-backuped
from_lsn = 0
to_lsn = 1635102
last_lsn = 1635102
recover_binlog_info = 0
```

See below for a description of the fields.

If the `--extra-lsndir` option is provided, then an extra copy of this file are saved in that directory.

< 11.1

`xtrabackup_checkpoints`

The `xtrabackup_checkpoints` file contains metadata about the backup.

For example:

```
backup_type = full-backuped
from_lsn = 0
to_lsn = 1635102
last_lsn = 1635102
recover_binlog_info = 0
```

See below for a description of the fields.

If the `--extra-lsndir` option is provided, then an extra copy of this file are saved in that directory.

`backup_type`

If the backup is a non-prepared full backup or a non-prepared partial backup, then `backup_type` is set to `full-backuped`.

If the backup is a non-prepared incremental backup, then `backup_type` is set to `incremental`.

If the backup has already been prepared, then `backup_type` is set to `log-applied`.

`from_lsn`

If `backup_type` is `full-backuped`, then `from_lsn` has the value of `0`.

If `backup_type` is `incremental`, then `from_lsn` has the value of the log sequence number (LSN) at which the backup started reading from the InnoDB redo log. This is internally used by mariadb-backup when preparing incremental backups.

This value can be manually set during an incremental backup with the –incremental-lsn option. However, it is generally better to let mariadb-backup figure out the `from_lsn` automatically by specifying a parent backup with the `--incremental-basedir` option.

`to_lsn`

`to_lsn` has the value of the log sequence number (LSN) of the last checkpoint in the InnoDB redo log. This is internally used by mariadb-backup when preparing incremental backups.

`last_lsn`

`last_lsn` has the value of the last log sequence number (LSN) read from the InnoDB redo log. This is internally used by mariadb-backup when preparing incremental backups.

CURRENT

`mariadb_backup_info`

Contains information about the backup. The fields in this file are listed below.

If the `--extra-lsndir` option is provided, an extra copy of this file is saved in that directory.

< 11.1

`xtrabackup_info`

Contains information about the backup. The fields in this file are listed below.

If the `--extra-lsndir` option is provided, an extra copy of this file is saved in that directory.

`uuid`

If a UUID was provided by the –incremental-history-uuid option, then it are saved here. Otherwise, this is the empty string.

`name`

If a name was provided by the `--history` or the `---incremental-history-name` options, then it are saved here. Otherwise, this is the empty string.

`tool_name`

The name of the mariadb-backup executable that performed the backup. This is generally `mariadb-backup`.

`tool_command`

The arguments that were provided to mariadb-backup when it performed the backup.

`tool_version`

The version of mariadb-backup that performed the backup.

`ibbackup_version`

The version of mariadb-backup that performed the backup.

`server_version`

The version of MariaDB Server that was backed up.

`start_time`

The time that the backup started.

`end_time`

The time that the backup ended.

`lock_time`

The amount of time that mariadb-backup held its locks.

`binlog_pos`

This field stores the binary log file name and position that corresponds to the backup.

This field also stores the value of the `gtid_current_pos` system variable that correspond to the backup.

The values in this field are only guaranteed to be consistent with the backup if the `--no-lock` option was **not** provided when the backup was taken.

`innodb_from_lsn`

This is identical to `from_lsn` in `xtrabackup_checkpoints`.

If the backup is a full backup, then `innodb_from_lsn` has the value of `0`.

If the backup is an incremental backup, then `innodb_from_lsn` has the value of the log sequence number (LSN) at which the backup started reading from the InnoDB redo log.

`innodb_to_lsn`

This is identical to `to_lsn` in `xtrabackup_checkpoints`.

`innodb_to_lsn` has the value of the log sequence number (LSN) of the last checkpoint in the InnoDB redo log.

`partial`

If the backup is a partial backup, then this value are `Y`.

Otherwise, this value are `N`.

`incremental`

If the backup is an incremental backup, then this value are `Y`.

Otherwise, this value are `N`.

`format`

This field's value is the format of the backup.

If the `--stream` option was set to `xbstream`, then this value are `xbstream`.

If the `--stream` option was **not** provided, then this value are `file`.

`compressed`

If the `--compress` option was provided, then this value are `compressed`.

Otherwise, this value are `N`.

> **CURRENT**
>
> **`mariadb_backup_slave_info`**
>
> If the `--slave-info` option is provided, this file contains the `CHANGE MASTER` command that can be used to set up a new server as a slave of the original server's master after the backup has been restored.
>
> `mariadb-backup` does **not** check if GTIDs are being used in replication. It takes a shortcut and assumes that if the gtid_slave_pos system variable is non-empty, then it writes the `CHANGE MASTER` command with the `MASTER_USE_GTID` option set to `slave_pos`. Otherwise, it writes the `CHANGE MASTER` command with the `MASTER_LOG_FILE` and `MASTER_LOG_POS` options using the master's binary log file and position. See MDEV-19264 for more information.
>
> **< 11.1**
>
> **`xtrabackup_slave_info`**

If the `--slave-info` option is provided, this file contains the `CHANGE MASTER` command that can be used to set up a new server as a slave of the original server's master after the backup has been restored.

`mariadb-backup` does **not** check if GTIDs are being used in replication. It takes a shortcut and assumes that if the gtid_slave_pos system variable is non-empty, then it writes the `CHANGE MASTER` command with the `MASTER_USE_GTID` option set to `slave_pos`. Otherwise, it writes the `CHANGE MASTER` command with the `MASTER_LOG_FILE` and `MASTER_LOG_POS` options using the master's binary log file and position. See MDEV-19264 for more information.

CURRENT

`mariadb_backup_galera_info`

If the `--galera-info` option is provided, this file contains information about a Galera Cluster node's state.

The file contains the values of the wsrep_local_state_uuid and wsrep_last_committed status variables.

The values are written in the following format:

```
wsrep_local_state_uuid:wsrep_last_committed
```

For example:

```
d38587ce-246c-11e5-bcce-6bbd0831cc0f:1352215
```

< 11.1

`xtrabackup_galera_info`

If the `--galera-info` option is provided, this file contains information about a Galera Cluster node's state.

The file contains the values of the wsrep_local_state_uuid and wsrep_last_committed status variables.

The values are written in the following format:

```
wsrep_local_state_uuid:wsrep_last_committed
```

For example:

```
d38587ce-246c-11e5-bcce-6bbd0831cc0f:1352215
```

`<table>.delta`

If the backup is an incremental backup, this file contains changed pages for the table.

`<table>.delta.meta`

If the backup is an incremental backup, this file contains metadata about `<table>.delta` files. The fields in this file are listed below.

`page_size`

This field contains either the value of `innodb_page_size` or the value of the `KEY_BLOCK_SIZE` table option for the table if the `ROW_FORMAT` table option for the table is set to `COMPRESSED`.

`zip_size`

If the `ROW_FORMAT` table option for this table is set to `COMPRESSED`, this field contains the value of the compressed page size.

`space_id`

This field contains the value of the table's `space_id`.

This page is licensed: CC BY-SA / Gnu FDL

Using Encryption and Compression Tools With mariadb-backup

> **Note:**
>
> mariadb-backup was previously called mariabackup.

`mariadb-backup` supports streaming to stdout with the `--stream=xbstream` option. This option allows easy integration with popular encryption and compression tools. Below are several examples.

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

Encrypting and Decrypting Backup With openssl

The following example creates an AES-encrypted backup, protected with the password "mypass" and stores it in a file "backup.xb.enc":

```
mariadb-backup --user=root --backup --stream=xbstream  | openssl  enc -aes-256-cbc -k mypass >
backup.xb.enc
```

To decrypt and unpack this backup into the current directory, the following command can be used:

```
openssl  enc -d -aes-256-cbc -k mypass -in backup.xb.enc | mbstream -x
```

Compressing and Decompressing Backup With gzip

This example compresses the backup without encrypting:

```
mariadb-backup --user=root --backup --stream=xbstream | gzip > backupstream.gz
```

We can decompress and unpack the backup as follows:

```
gunzip -c backupstream.gz | mbstream -x
```

Compressing and Encrypting Backup, Using gzip and openssl

This example adds a compression step before the encryption, otherwise looks almost identical to the previous example:

```
mariadb-backup --user=root --backup --stream=xbstream | gzip | openssl  enc -aes-256-cbc -k mypass >
backup.xb.gz.enc
```

We can decrypt, decompress and unpack the backup as follow (note `gzip -d` in the pipeline):

```
openssl  enc -d -aes-256-cbc -k mypass -in backup.xb.gz.enc |gzip -d| mbstream -x
```

Compressing and Encrypting with 7Zip

7zip archiver is a popular utility (especially on Windows) that supports reading from standard output, with the `-si` option, and writing to stdout with the `-so` option, and can thus be used together with mariadb-backup.

Compressing backup with the 7z command line utility works as follows:

```
mariadb-backup --user=root --backup --stream=xbstream | 7z a -si backup.xb.7z
```

Uncompress and unpack the archive with

```
7z e backup.xb.7z -so |mbstream -x
```

7z also has builtin AES-256 encryption. To encrypt the backup from the previous example using password SECRET, add `-pSECRET` to the 7z command line.

Compressing with zstd

Compress

```
mariadb-backup --user=root --backup --stream=xbstream  | zstd - -o backup.xb.zst -f -1
```

Decompress, unpack

```
zstd -d backup.xbstream.zst -c | mbstream -x
```

Encrypting With GPG

Encryption

```
mariadb-backup --user=root --backup --stream=xbstream | gpg -c --passphrase SECRET --batch --yes -o
backup.xb.gpg
```

Decrypt, unpack

```
gpg --decrypt --passphrase SECRET --batch --yes  backup.xb.gpg | mbstream -x
```

Interactive Input for Passphrases

Most of the described tools also provide a way to enter a passphrase interactively (although 7zip does not seem to work well when reading input from stdin). Please consult documentation of the tools for more info.

Writing extra status files

By default files like xtrabackup_checkpoints are also written to the output stream only, and so would not be available for taking further incremental backups without prior extraction from the compressed or encrypted stream output file.

To avoid this these files can additionally be written to a directory that can then be used as input for further incremental backups using the –extra-lsndir=… option.

See also e.g: Combining incremental backups with streaming output

Encrypted Files Backup (mariadb-backup)

This page addresses a major misconception: Many users assume that, because `mariadb-backup` reads encrypted files, it “unlocks” them. However, the encryption remains intact throughout the entire lifecycle, as explained in the following.

Compatibility with Data-at-Rest Encryption (TDE)

While this page primarily discusses using external tools like `openssl` to encrypt a backup stream, `mariadb-backup` is also fully compatible with MariaDB’s internal data-at-rest encryption (TDE) for InnoDB and Aria tables.

When backing up a server where encryption is enabled, there are specific behaviors and requirements during the backup, prepare, and restore phases.

1. The Backup Phase

When `mariadb-backup` performs a backup, it copies the physical files exactly as they exist on disk. If the files are encrypted at rest by the MariaDB server, the backup files remain encrypted.

- **No “double encryption” required:** You do not *need* to pipe the backup through `openssl` to secure it, as the data is already encrypted. However, you may still choose to do so for additional security or to encrypt non-InnoDB files (like configuration files or metadata).
- **Key Access:** `mariadb-backup` must be able to read the encrypted files. In order to do that, `mariadb-backup` queries the server as to what encryption plugin is used:

```
SELECT plugin_name, plugin_library, @@plugin_dir FROM information_schema.plugins WHERE
plugin_type='ENCRYPTION';
+---------------------+-----------------------+--------------------------------------+
| plugin_name         | plugin_library        | @@plugin_dir                         |
+---------------------+-----------------------+--------------------------------------+
| file_key_management | file_key_management.so | /opt/homebrew/opt/mariadb/lib/plugin/ |
+---------------------+-----------------------+--------------------------------------+
```

Once `mariadb-backup` knows that `file_key_management` is used, it queries the server for details, like the location of the key file, and which encryption algorithm is used:

```
SHOW VARIABLES LIKE 'file_key_management%';
+----------------------------------------+-------------------------------------------------+
| Variable_name                          | Value                                           |
+----------------------------------------+-------------------------------------------------+
| file_key_management_digest             | sha1                                            |
| file_key_management_encryption_algorithm | aes_ctr                                       |
| file_key_management_filekey            |                                                 |
| file_key_management_filename           | /opt/homebrew/etc/mysql/encryption/keyfile.txt |
| file_key_management_use_pbkdf2         | 0                                               |
+----------------------------------------+-------------------------------------------------+
```

`mariadb-backup` uses that information to calculate the checksums of `.ibd` files/pages, and to decrypt the redo log for further information.

2. The Prepare Phase

The “Prepare” phase is when `mariadb-backup` makes the data consistent by applying the redo logs.

- **Requirement:** To perform the prepare phase, the tool *must* have access to the same encryption keys used by the server at the time of the backup.
- **Persistence:** After the prepare phase is complete, the data files *remain encrypted*. The tool does not “decrypt” the database into plain text; it only ensures the encrypted pages are consistent.

3. The Restore Phase

The restore phase simply moves the encrypted files back to the target server's data directory.

> **Warning:**
>
> **CRITICAL LIMITATION:** A restore is **only** successful if the target server is configured with the **exact same keys** and KMS method used by the original server. If the target server has a different key or cannot load the key management plugin, the MariaDB service fails to start, or tables are marked as "corrupted" because the engine cannot decrypt the pages.

TDE Backup Requirements Checklist

To ensure a restorable backup of an encrypted MariaDB instance, you must:

1. **Access to encryption information:** Ensure that `mariadb-backup` has the same access to encryption information as the server does.
2. **Back up the keys:** The encryption keys themselves are **not** stored inside the backup. You must manually back up your `keyfile.txt`, AWS KMS credentials, or HashiCorp Vault tokens separately.
3. **Synchronize target keys:** Before running `mariadb-backup --copy-back`, verify that the destination server's configuration points to the identical keys used during the backup.

Key Takeaways

- **Data State:** Encrypted at source → Encrypted in backup → Encrypted at destination.
- **Prepare Phase:** Needs the key to read/apply logs, but writes encrypted data back out.
- **Restoration:** If you lose your keys, your backup is permanently unrecoverable.

Mixed-Encryption Backups

Mixed-encryption backups are a common scenario, especially in large production environments where a full "rotation" (encrypting all old data) can take days or weeks.

`mariadb-backup` is "smart" enough to handle a mixed-state tablespace.

When you run a backup on a mixed-encryption database, here is exactly what happens under the hood:

1. File-by-File Detection

`mariadb-backup` reads the *header* of every tablespace file (`.ibd` files). Each header contains metadata that tells the tool whether that specific file is encrypted or plain text.

- If the header says "Encrypted," the tool uses the configured KMS keys to read the pages.
- If the header says "Plain Text," it reads them normally.

2. Preservation of State

The backup is an exact physical replica. This means:

- **Table A (Encrypted)** stays encrypted in the backup.
- **Table B (Unencrypted)** stays unencrypted in the backup. The backup does not "standardize" the encryption; it respects the individual state of each table at the exact moment the backup started.

3. The Prepare Phase in a Mixed Environment

This is where the KMS[6] configuration is vital. During the "Prepare" phase (`--prepare`), `mariadb-backup` applies the Redo Log to the tables to ensure consistency.

- If a transaction in the Redo Log involves an *encrypted* table, the tool uses the keys to apply that change.

- If the transaction involves an *unencrypted* table, it applies it without keys.
- **The Result:** After the prepare phase, your backup remains in a mixed state, exactly matching the original source.

Key Limitations & Risks for Mixed Backups

Scenario	Behavior	Risk
Missing Keys	The backup fails or the `prepare` phase crashes when it hits the first encrypted table.	Even if 99% of your tables are unencrypted, 1 encrypted table requires the KMS to be active for the backup to be valid.
New Tables	If you enable encryption *during* a long-running backup, `mariadb-backup` handles it via the Redo Log.	Ensure the key used for the new table is the same one available to the backup tool.
Restore Target	You restore to a server without a KMS plugin.	The unencrypted tables work fine, but the encrypted tables are unreadable/corrupted.

> **Note:**
>
> **Note on Mixed Environments:** `mariadb-backup` supports databases containing a mix of encrypted and unencrypted tables. The tool detects the encryption status of each tablespace individually. However, if even a single table in the backup is encrypted, the **entire** `--prepare` process requires access to the Key Management System (KMS). Without valid keys, the tool cannot verify the consistency of encrypted tables, and the backup preparation fails.

Handling Mixed-Encryption Environments

In many production environments, a database may contain a mix of encrypted and unencrypted tables. This occurs frequently during a rolling migration to TDE or when only specific sensitive tables are targeted for encryption.

1. Tablespace Detection

`mariadb-backup` detects the encryption status of each tablespace individually by reading the file headers. It does not “force” encryption on unencrypted tables, nor does it decrypt encrypted ones. The backup is an exact physical replica of the source’s mixed state.

2. The Prepare Phase Requirement

Even if only one table in your database is encrypted, the **entire** `--prepare` phase requires the Key Management System (KMS) to be active and configured. The tool must be able to read the encryption keys to apply redo logs and ensure consistency across the entire dataset. If the KMS is unavailable, the prepare phase fails.

3. Best Practice: Layered Encryption

Because a mixed-state backup leaves unencrypted tables (and database metadata) vulnerable in the backup file, it is a recommended best practice to use **Layered Encryption**.

By piping the `mariadb-backup` stream through an external encryption tool (like OpenSSL), you ensure that:

- **Legacy/Unencrypted tables** are protected within the backup archive.
- **Metadata** (file names, schemas, and logs) is hidden.
- **Transport Security** is maintained regardless of the destination server’s TDE configuration.

Example: Encrypting a Mixed-State Backup Stream

```
mariadb-backup --backup --stream=xbstream | \ openssl enc -aes-256-cbc -k $BACKUP_PASSWORD >
full_secure_backup.xb.enc
```

> **Warning:**
>
> **Warning:** When using Layered Encryption, the restoration process requires **two** sets of credentials: the external password/key to decrypt the stream, and the MariaDB KMS keys to prepare and run the database. Loss of either set renders the backup unrecoverable.

Summary of TDE Backup Behavior

Component	State in Backup	Requires KMS for Prepare?
Encrypted InnoDB Table	Encrypted	**Yes**
Plaintext InnoDB Table	Plaintext	**Yes** (to initialize engine)
Aria System Tables	Encrypted (if configured)	**Yes**
Binary / Redo Logs	Encrypted (if configured)	**Yes**
Backup Metadata	Plaintext	No

How mariadb-backup Works

> **Note:**
>
> mariadb-backup was previously called mariabackup.

This is a description of the different stages in `mariadb-backup`, what they do and why they are needed.

Execution Stages

Initialization Phase

- Connect to mysqld instance, find out important variables (`datadir`, InnoDB pagesize, encryption keys, encryption plugin etc)
- Scan the database directory, `datadir`, looking for InnoDB tablespaces, load the tablespaces (basically, it is an “open” in InnoDB sense)
- If `--lock-ddl-per-table` is used:
  - Do MDL locks, for InnoDB tablespaces that we want to copy. This is to ensure that there are no `ALTER`, `RENAME` , `TRUNCATE` or `DROP TABLE` on any of the tables that we want to copy.
  - This is implemented with:

```
BEGIN
FOR EACH affected TABLE
SELECT 1 FROM <TABLE> LIMIT 0
```

- If lock-ddl-per-table is not done, then mariadb-backup would have to know all tables that were created or altered during the backup. See MDEV-16791.

Redo Log Handling

Start a dedicated thread in mariadb-backup to copy InnoDB redo log (`ib_logfile*`).

- This is needed to record all changes done while the backup is running. (The redo log logically is a single circular file, split into `innodb_log_files_in_group` files.)
- The log is also used to see detect if any truncate or online alter tables are used.
- The assumption is that the copy thread are able to keep up with server. It should always be able keep up, if the redo log is big enough.

Copy-phase for InnoDB Tablespaces

- Copy all selected tablespaces, file by file, in dedicated threads in mariadb-backup without involving the mysqld server.
- This is special “careful” copy, it looks for page-level consistency by checking the checksum.
- The files are not point-in-time consistent as data may change during copy.
- The idea is that InnoDB recovery would make it point-in-time consistent.

Create a Consistent Backup Point

- Execute `FLUSH TABLE WITH READ LOCK`. This is default, but may be omitted with the `--no-lock` parameter. The reason why `FLUSH` is needed is to ensure that all tables are in a consistent state at the exact same point in time, independent of storage engine.
- If `--lock-ddl-per-table` is used and there is a user query waiting for MDL, the user query are killed to resolve a deadlock. Note that these are only queries of type `ALTER`, `DROP`, `TRUNCATE` or RENAME `TABLE`. (MDEV-15636)

Last Copy Phase

- Copy `.frm`, `MyISAM`, `Aria` and other storage engine files.
- If `MyRocks` is used, create rocksdb checkpoint via the `set rocksdb_create_checkpoint=$rocksdb_data_dir/mariadb-backup_rocksdb_checkpoint` command. The result of it is a directory with hardlinks to MyRocks files. Copy the checkpoint directory to the backup (or create hardlinks in backup directory is on the same partition as data directory). Remove the checkpoint directory.
- Copy tables that were created while the backup was running and do rename files that were changed during backup (since MDEV-16791).
- Copy the rest of InnoDB redo log, stop redo-log-copy thread.
- Write some metadata info (binlog position).

Release Locks

- If `FLUSH TABLE WITH READ LOCK` was done:
  - execute: `UNLOCK TABLES`
- If `--lock-ddl-per-table` was done:
  - execute `COMMIT`

Handle Log Tables (TODO)

- If log tables exists:
  - Take MDL lock for log tables
  - Copy part of log tables that wasn’t copied before
  - Unlock log tables

Notes

- If `FLUSH TABLE WITH READ LOCK` is not used, only InnoDB tables are consistent (not the privilege tables in the mysql database or the binary log). The backup point depends on the content of the redo log within the backup itself.

mariadb-backup and BACKUP STAGE

> **Note:**
>
> mariadb-backup was previously called mariabackup.

The BACKUP STAGE statements make it possible to make an efficient external backup tool. How `mariadb-backup` uses these statements depends on whether you are using the version that is bundled with MariaDB Community Server or the version that is bundled with MariaDB Enterprise Server.

> **Note:**
>
> For a complete list of `mariadb-backup` options, see this page.
>
> For a detailed description of `mariadb-backup` functionality, see this page.

`BACKUP STAGE` in MariaDB Community Server

The BACKUP STAGE statements are supported. However, the version of `mariadb-backup` that is bundled with MariaDB Community Server does not yet use the `BACKUP STAGE` statement in the most efficient way. `mariadb-backup` simply executes the following `BACKUP STAGE` statement to lock the database:

```
BACKUP STAGE START;
BACKUP STAGE BLOCK_COMMIT;
```

When the backup is complete, it executes the following `BACKUP STAGE` statement to unlock the database:

```
BACKUP STAGE END;
```

> **Note:**
>
> To use a version of `mariadb-backup` that uses the BACKUP STAGE statements in the most efficient way, use MariaDB Backup bundled with MariaDB Enterprise Server.

Tasks Performed Prior to `BACKUP STAGE` in MariaDB Community Server

- Copy some transactional tables.
  - InnoDB (i.e. `ibdataN` and file extensions `.ibd` and `.isl`)
- Copy the tail of some transaction logs.
  - The tail of the InnoDB redo log (i.e. `ib_logfileN` files) are copied for InnoDB tables.

`BACKUP STAGE START` in MariaDB Community Server

`mariadb-backup` from MariaDB Community Server does not perform any tasks in the `START` stage.

`BACKUP STAGE FLUSH` in MariaDB Community Server

`mariadb-backup` from MariaDB Community Server does not currently perform any tasks in the `FLUSH` stage.

`BACKUP STAGE BLOCK_DDL` in MariaDB Community Server

`mariadb-backup` from MariaDB Community Server does not currently perform any tasks in the `BLOCK_DDL` stage.

`BACKUP STAGE BLOCK_COMMIT` in MariaDB Community Server

`mariadb-backup` from MariaDB Community Server performs the following tasks in the `BLOCK_COMMIT` stage:

- Copy other files.

    - i.e. file extensions `.frm`, `.isl`, `.TRG`, `.TRN`, `.opt`, `.par`
- Copy some transactional tables.
    - Aria (i.e. `aria_log_control` and file extensions `.MAD` and `.MAI`)
- Copy the non-transactional tables.
    - `MyISAM` (i.e. file extensions `.MYD` and `.MYI`)
    - `MERGE` (i.e. file extensions `.MRG`)
    - `ARCHIVE` (i.e. file extensions `.ARM` and `.ARZ`)
    - `CSV` (i.e. file extensions `.CSM` and `.CSV`)
- Create a MyRocks checkpoint using the `rocksdb_create_checkpoint` system variable.
- Copy the tail of some transaction logs.
    - The tail of the InnoDB redo log (i.e. `ib_logfileN` files) are copied for InnoDB tables.
- Save the binary log position to `xtrabackup_binlog_info`.
- Save the Galera Cluster state information to `xtrabackup_galera_info`.

`BACKUP STAGE END` in MariaDB Community Server

`mariadb-backup` from MariaDB Community Server performs the following tasks in the `END` stage:

- Copy the MyRocks checkpoint into the backup.

`BACKUP STAGE` in MariaDB Enterprise Server

The following sections describe how the MariaDB Backup version of mariadb-backup that is bundled with MariaDB Enterprise Server uses each BACKUP STAGE statement in an efficient way.

`BACKUP STAGE START` in MariaDB Enterprise Server

`mariadb-backup` from MariaDB Enterprise Server performs the following tasks in the `START` stage:

- Copy all transactional tables.
    - InnoDB (i.e. `ibdataN` and file extensions `.ibd` and `.isl`)
    - Aria (i.e. `aria_log_control` and file extensions `.MAD` and `.MAI`)
- Copy the tail of all transaction logs.
    - The tail of the InnoDB redo log (i.e. `ib_logfileN` files) are copied for InnoDB tables.
    - The tail of the Aria redo log (i.e. `aria_log.N` files) are copied for Aria tables.

`BACKUP STAGE FLUSH` in MariaDB Enterprise Server

mariadb-backup from MariaDB Enterprise Server performs the following tasks in the `FLUSH` stage:

- Copy all non-transactional tables that are not in use. This list of used tables is found with `SHOW OPEN TABLES`.
    - `MyISAM` (i.e. file extensions `.MYD` and `.MYI`)
    - `MERGE` (i.e. file extensions `.MRG`)
    - `ARCHIVE` (i.e. file extensions `.ARM` and `.ARZ`)
    - `CSV` (i.e. file extensions `.CSM` and `.CSV`)
- Copy the tail of all transaction logs.
    - The tail of the InnoDB redo log (i.e. `ib_logfileN` files) are copied for InnoDB tables.
    - The tail of the Aria redo log (i.e. `aria_log.N` files) are copied for Aria tables.

`BACKUP STAGE BLOCK_DDL` in MariaDB Enterprise Server

`mariadb-backup` from MariaDB Enterprise Server performs the following tasks in the `BLOCK_DDL` stage:

- Copy other files.
  - i.e. file extensions `.frm`, `.isl`, `.TRG`, `.TRN`, `.opt`, `.par`
- Copy the non-transactional tables that were in use during `BACKUP STAGE FLUSH`.
  - `MyISAM` (i.e. file extensions `.MYD` and `.MYI`)
  - `MERGE` (i.e. file extensions `.MRG`)
  - `ARCHIVE` (i.e. file extensions `.ARM` and `.ARZ`)
  - `CSV` (i.e. file extensions `.CSM` and `.CSV`)
- Check `ddl.log` for DDL executed before the `BLOCK DDL` stage.
  - The file names of newly created tables can be read from `ddl.log`.
  - The file names of dropped tables can also be read from `ddl.log`.
  - The file names of renamed tables can also be read from `ddl.log`, so the files can be renamed instead of re-copying them.
- Copy changes to system log tables.
  - mysql.general_log
  - mysql.slow_log
  - This is easy as these are append only.
- Copy the tail of all transaction logs.
  - The tail of the InnoDB redo log (i.e. `ib_logfileN` files) are copied for InnoDB tables.
  - The tail of the Aria redo log (i.e. `aria_log.N` files) are copied for Aria tables.

`BACKUP STAGE BLOCK_COMMIT` in MariaDB Enterprise Server

`mariadb-backup` from MariaDB Enterprise Server performs the following tasks in the `BLOCK_COMMIT` stage:

- Create a MyRocks checkpoint using the rocksdb_create_checkpoint system variable.
- Copy changes to system log tables.
  - mysql.general_log
  - mysql.slow_log
  - This is easy as these are append only.
- Copy changes to statistics tables.
  - mysql.table_stats
  - mysql.column_stats
  - mysql.index_stats
- Copy the tail of all transaction logs.
  - The tail of the InnoDB redo log (i.e. `ib_logfileN` files) are copied for InnoDB tables.
  - The tail of the Aria redo log (i.e. `aria_log.N` files) are copied for Aria tables.
- Save the binary log position to `xtrabackup_binlog_info`.
- Save the Galera Cluster state information to `xtrabackup_galera_info`.

`BACKUP STAGE END` in MariaDB Enterprise Server

`mariadb-backup` from MariaDB Enterprise Server performs the following tasks in the `END` stage:

- Copy the MyRocks checkpoint into the backup.

This page is licensed: CC BY-SA / Gnu FDL

Point-In-Time Recovery (InnoDB Log Archiving)

> **Note:**
>
> This functionality is available from MariaDB 13.0.

When InnoDB log archiving is enabled, the server retains a continuous history of write-ahead log records across multiple `ib_lsn.log` files. You can use this history to perform point-in-time recovery (PITR) to a specific Log Sequence Number (LSN), by replaying the archived InnoDB write-ahead logs at server startup.

This is an alternative to PITR via mariadb-backup and binary logs, useful in InnoDB-only deployments or in recovery scenarios where binary logs are not available.

> **Warning:**
>
> No shipped backup tool yet generates or restores backups in the `innodb_log_archive=ON` format — `mariadb-backup` does not support it and fails when the server is running with `innodb_log_archive=ON`. A backup tool that uses this format is being worked on. Until it ships, this procedure assumes you already have an externally-prepared restore that contains a consistent set of `ib_lsn.log` files alongside the InnoDB data files.

Recovery Parameters

Two startup parameters define the range of the log replay:

- `innodb_log_recovery_start` — the LSN at which recovery begins. Set this to the end LSN of the previous restore when applying an incremental restore. The default `0` starts from the latest completed checkpoint, which is guaranteed to live in one of the last two `ib_lsn.log` files.
- `innodb_log_recovery_target` — the LSN at which recovery ends (the recovery point objective). When this is non-zero, persistent InnoDB tables become read-only and no log writes are allowed during the recovery session. The default `0` replays the log to its end.

You can identify candidate LSNs from the `Innodb_lsn_archived` status variable on the source server, and from the file names in the data directory (each `ib_lsn.log` file name encodes the LSN at file offset `0x3000`).

The data files in the restore must correspond to an LSN that lies between `Innodb_lsn_archived` (the first checkpoint in the first archived log file) and the end LSN of the last archived log file. To extend the available recovery range, copy additional archived log files in from the source server — no further copying of data files is required.

Procedure

> **Step 1**
>
> **Prepare the restore.**
>
> Place the restored InnoDB data files and the corresponding `ib_lsn.log` archive files in the data directory. With `innodb_log_archive=ON`, the server refuses to start if a legacy `ib_logfile0` exists, so make sure it is not present.

> **Step 2**
>
> **Stop the MariaDB Server (if it is running).**

```
$ sudo systemctl stop mariadb
```

Step 3

Start the server with recovery parameters.

Pass `innodb_log_recovery_start` and `innodb_log_recovery_target` either on the command line or in the configuration file, alongside `innodb_log_archive=ON`. While `innodb_log_recovery_target` is non-zero, the server replays the archived log up to the target LSN and then keeps the InnoDB tables read-only.

Step 4

Verify the state.

Once the server reaches the target LSN, the recovery process stops. Inspect `Innodb_lsn_archived`, `Innodb_lsn_current`, and the contents of the recovered tables to confirm the data is at the expected logical point.

Step 5

Resume normal operation.

To return to normal read-write operation, restart the server without `innodb_log_recovery_target` set.

Warning:

No data file may carry an LSN newer than `innodb_log_recovery_target`. Crash recovery's role is to bring every database page to the same LSN. If any data file is newer than the target, recovery completes in an inconsistent state where some pages carry an LSN past the target — the database is corrupted. The server cannot validate every such impossible target, and the resulting corruption may not surface until the affected pages are accessed (see MDEV-34830). See `innodb_log_recovery_target` for details.

Note:

Point-in-time recovery of DDL operations is limited even for an InnoDB-only deployment, because part of the data dictionary is stored in `.frm` files whose creation is not covered by the InnoDB write-ahead log.

Replication as a Backup Solution

Replication can be used to support the backup strategy.

Important:

Replication alone is *not* sufficient for backup. It assists in protecting against hardware failure on the primary server, but does not protect against data loss. An accidental or malicious `DROP DATABASE` or `TRUNCATE TABLE` statement are replicated onto the replica as well. Care needs to be taken to prevent data getting out of sync between the primary and the replica.

Note:

The terms *master* and *slave* have historically been used in replication, and MariaDB has begun the process of adding *primary* and *replica* synonyms. The old terms will continue to be used to maintain backward compatibility - see MDEV-18777 to follow progress on this effort.

Replication is most commonly used to support backups as follows:

- A primary server replicates to a replica
- Backups are then run off the replica without any impact on the primary.

Backups can have a significant effect on a server, and a high-availability primary may not be able to be stopped, locked or simply handle the extra load of a backup. Running the backup from a replica has the advantage of being able to shutdown or lock the replica and perform a backup without any impact on the primary server.

Note that when backing up off a replica server, it is important to ensure that the servers keep the data in sync. See for example Replication and Foreign Keys for a situation when identical statements can result in different data on a replica and a primary.

Setting Up a Dedicated Backup Replica

To set up a replica specifically for backup purposes, you will need to configure outbound replication from your primary server to the replica. Here is a step-by-step guide to establishing this connection securely:

1. Create a User for Replication

On the **primary server**, create a dedicated user for replication and grant it the necessary privileges:

```
CREATE USER 'backup_replica'@'replica_ip_or_hostname' IDENTIFIED BY 'strong_password';
GRANT REPLICATION SLAVE ON *.* TO 'backup_replica'@'replica_ip_or_hostname';
```

(Optional: Confirm the grants by executing `SHOW GRANTS FOR 'backup_replica'@'replica_ip_or_hostname';`)

2. Obtain the GTID Position

On the primary server, obtain the current GTID position from which the replica should start replicating. If you want to start from the most recent transaction, query the `gtid_current_pos`:

```
SHOW GLOBAL VARIABLES LIKE 'gtid_current_pos';
```

3. Configure the GTID Position on the Replica

On the replica server, configure the starting GTID position using the value obtained in the previous step:

SQL

```
SET GLOBAL gtid_slave_pos='<gtid_value_from_primary>';
```

4. Configure Replication

On the replica server, configure the connection to the primary server using the `CHANGE MASTER TO` statement:

```
CHANGE MASTER TO
   MASTER_HOST='primary_domain_or_ip',
   MASTER_PORT=3306,
   MASTER_USER='backup_replica',
   MASTER_PASSWORD='strong_password',
   MASTER_SSL=1,
   MASTER_USE_GTID=slave_pos;
```

(Note: Adjust the `MASTER_PORT`, `MASTER_SSL`, and add `MASTER_SSL_CA` parameters as necessary depending on your network and security configuration).

5. Start Replication

On the replica server, start the replication process:

```
START REPLICA;
```

6. Check Replication Status

On the replica server, verify that replication is running smoothly:

```
SHOW REPLICA STATUS \G
```

Ensure that both `Slave_IO_Running` and `Slave_SQL_Running` are `Yes`. Once the replica is fully synced, you can safely pause it or run your backup tools (`mariadb-backup` or `mariadb-dump`) directly against this replica without affecting the primary server's performance.

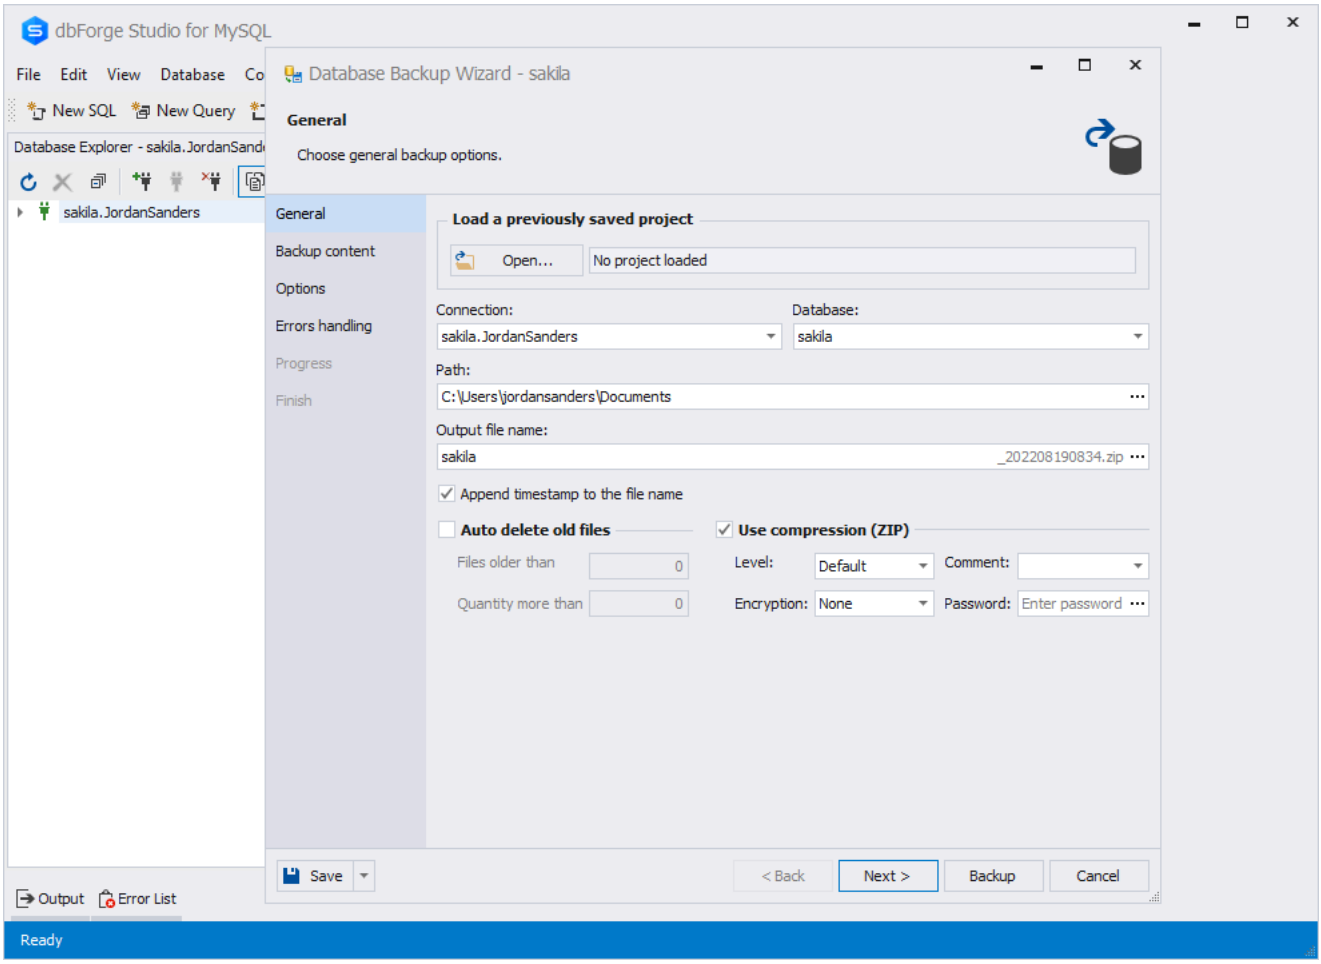
Backup and Restore via dbForge Studio

> **Note:**
>
> dbForge Studio is proprietary third-party software, not developed or maintained by MariaDB and not included with MariaDB Server. MariaDB doesn't test, validate, or support it. Content contributed by Devart; refer to its own documentation and license terms.

In the modern world, data importance is non-negotiable, and keeping data integrity and consistency is the top priority. Data stored in databases is vulnerable to system crashes, hardware problems, security breaches, and other failures causing data loss or corruption. To prevent database damage, it is important to back the data up regularly and implement the data restore policies.
MariaDB, one of the most popular database management systems, provides several methods to configure routines for backing up and recovering data. The current guideline illustrates both processes performed with the help of dbForge Studio for MySQL which is also a fully-functional GUI client for MariaDB that has everything you need to accomplish the database-related tasks on MariaDB.

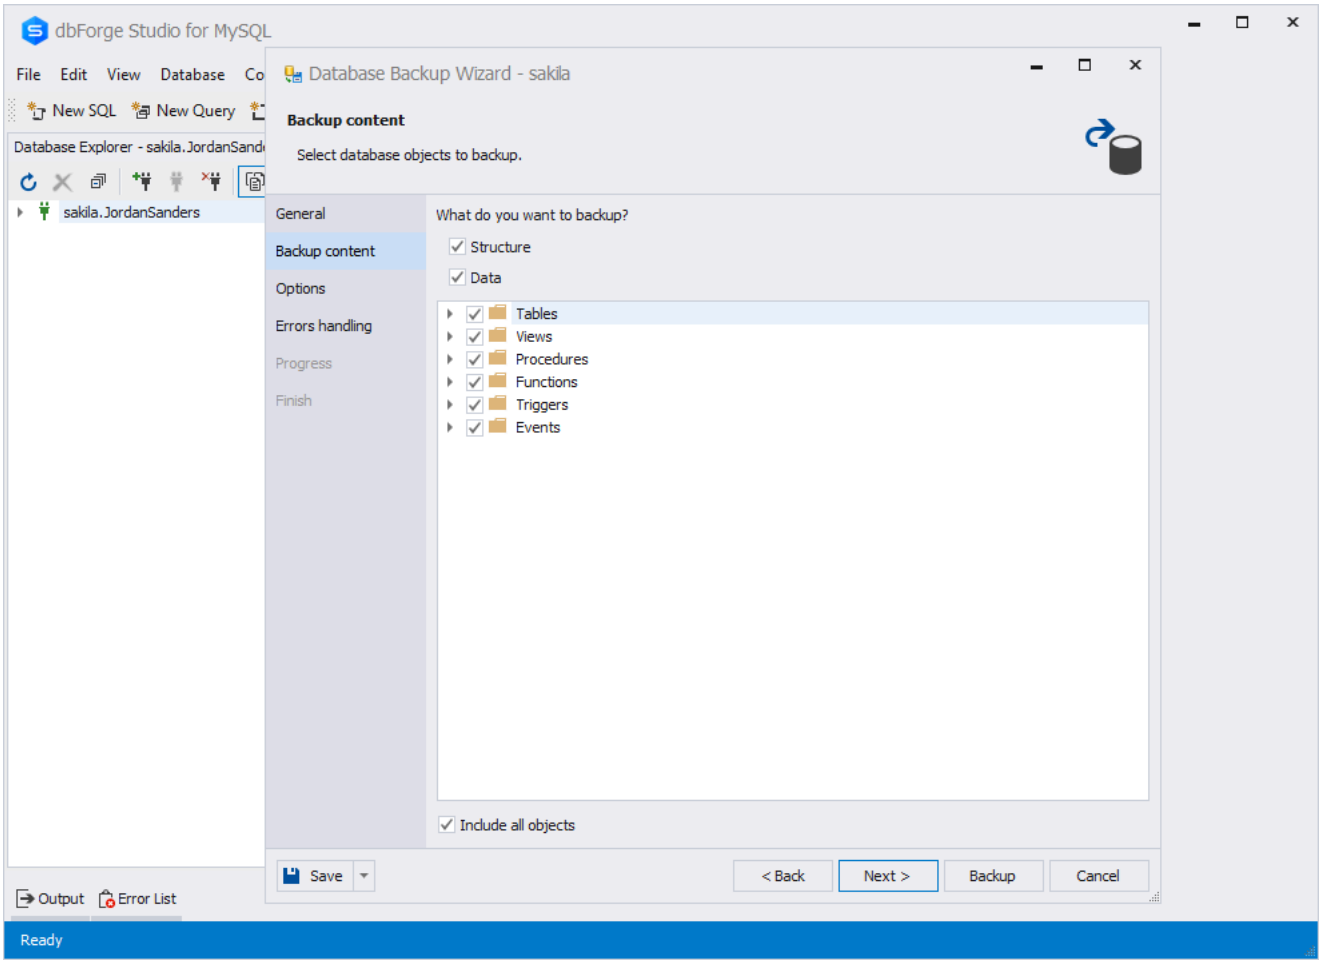
Create the backup on MariaDB

dbForge Studio for MySQL and MariaDB has a separate module dedicated to the data backing up and recovering jobs. Let us first look at how set the tool to create a MariaDB backup.
Launch the Studio and go to **Database > Backup and Restore > Backup Database**. The **Database Backup Wizard** with several pages will appear.
On the General page, specify the database in question and how to connect to it, then choose where to save the created backup file, and specify its name. There are additional optional settings – you can select to delete old files automatically, zip the output backup file, etc. When done, click **Next**.



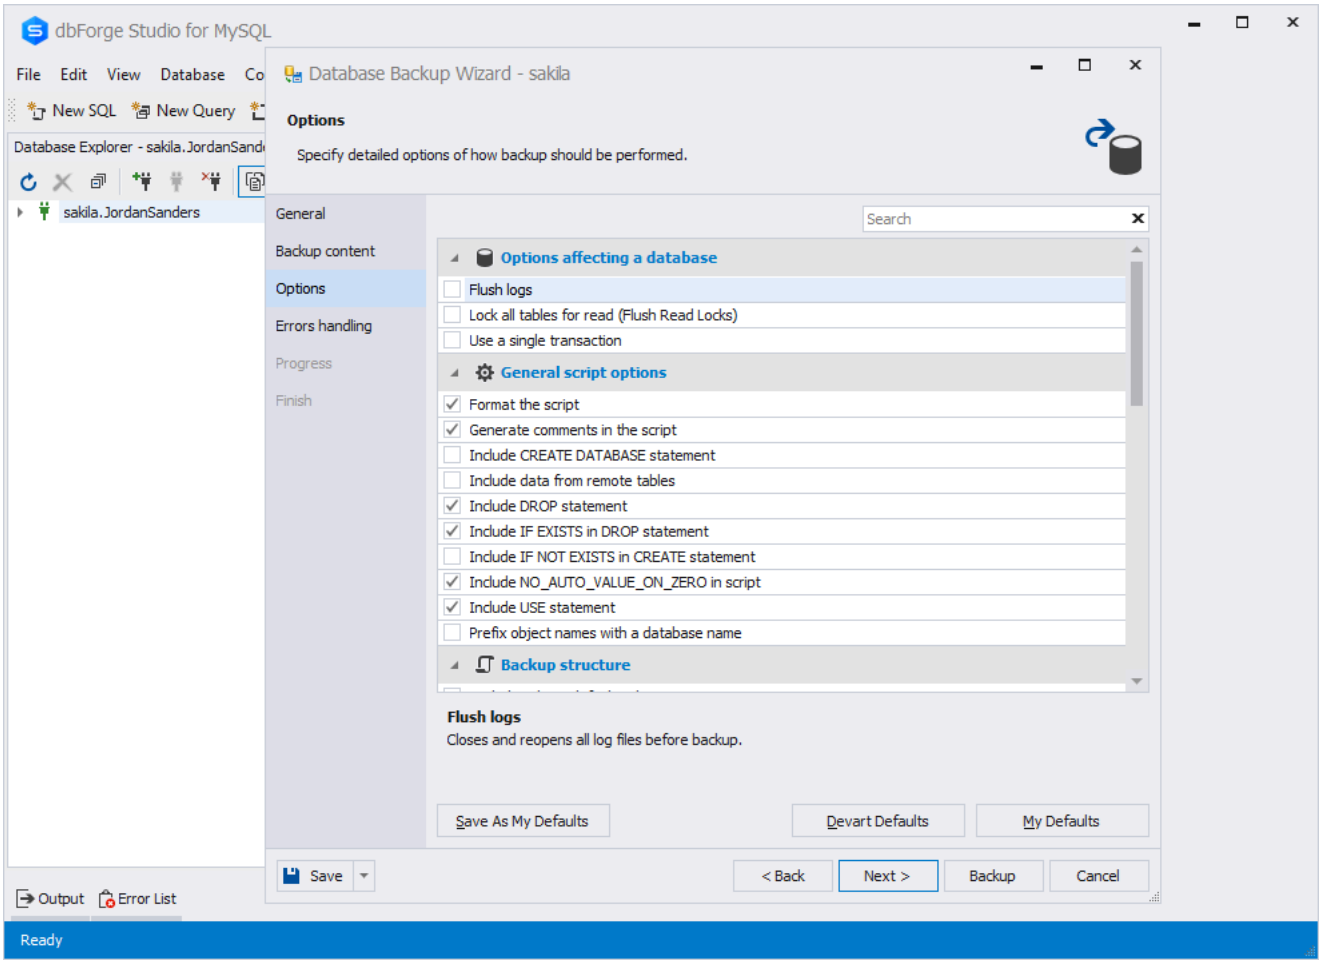
b1

On the **Backup content** page, select the objects to back up. Click **Next**.



b2

The **Options** page. Here you can specify the details of the data backing up process. Plenty of available options allow you to configure this task precisely to meet the specific requirements. When done, click **Next**.



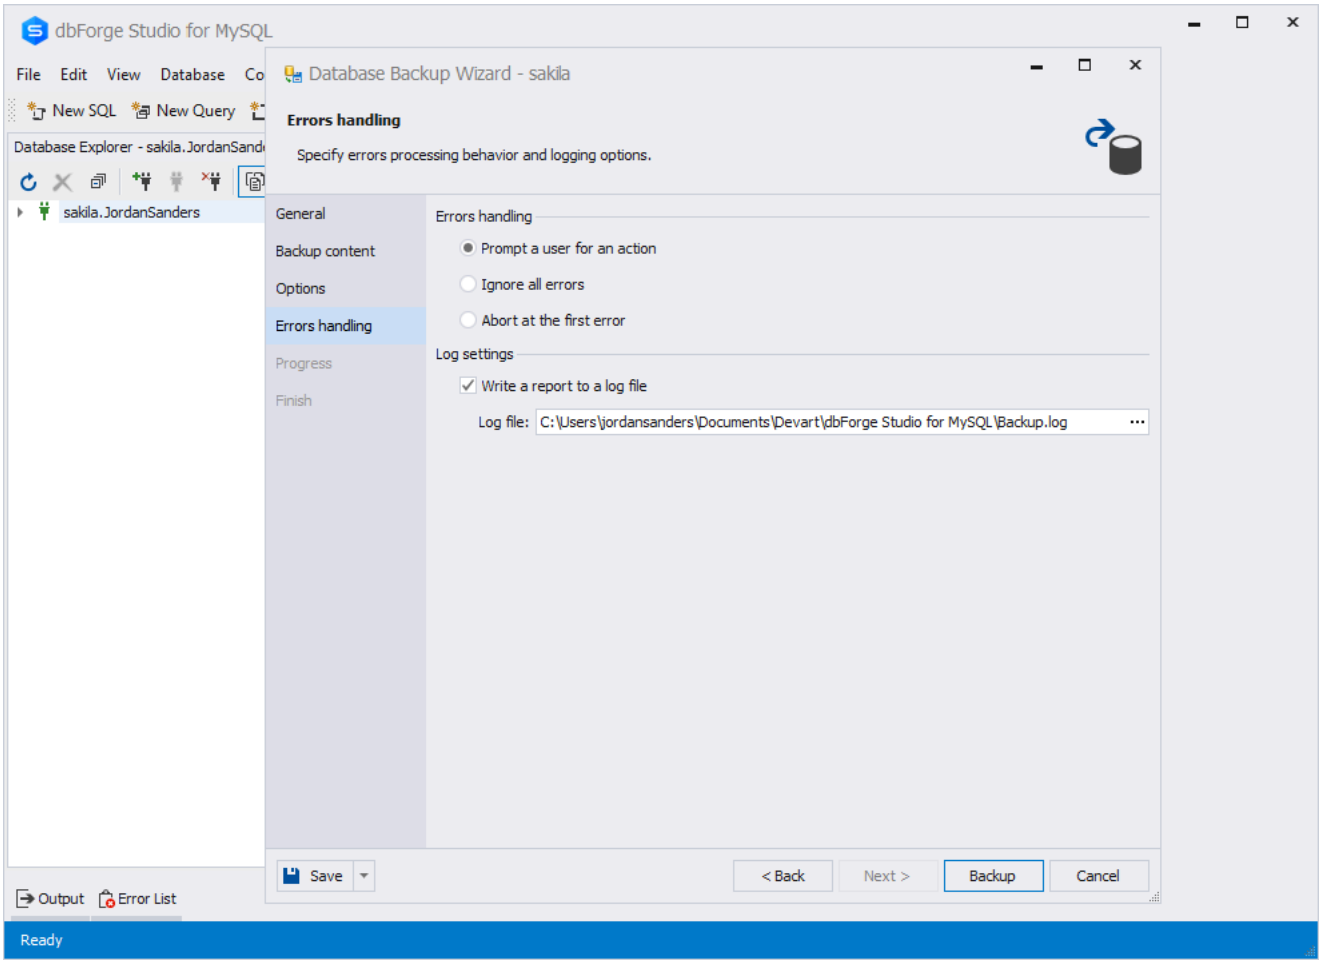
b3

The **Errors handling** page. Here you configure how the Studio should handle the errors that might occur during the backing up process. Also, you can set the Studio to write the information about the errors it encountered into the log file.

You can save the project settings to apply them in the future. For this, in the left bottom corner of the Wizard, select one of the saving options: **Save Project** or **Save Command Line**. The latter allows saving settings as a backup script which you can execute from the command line at any time later.

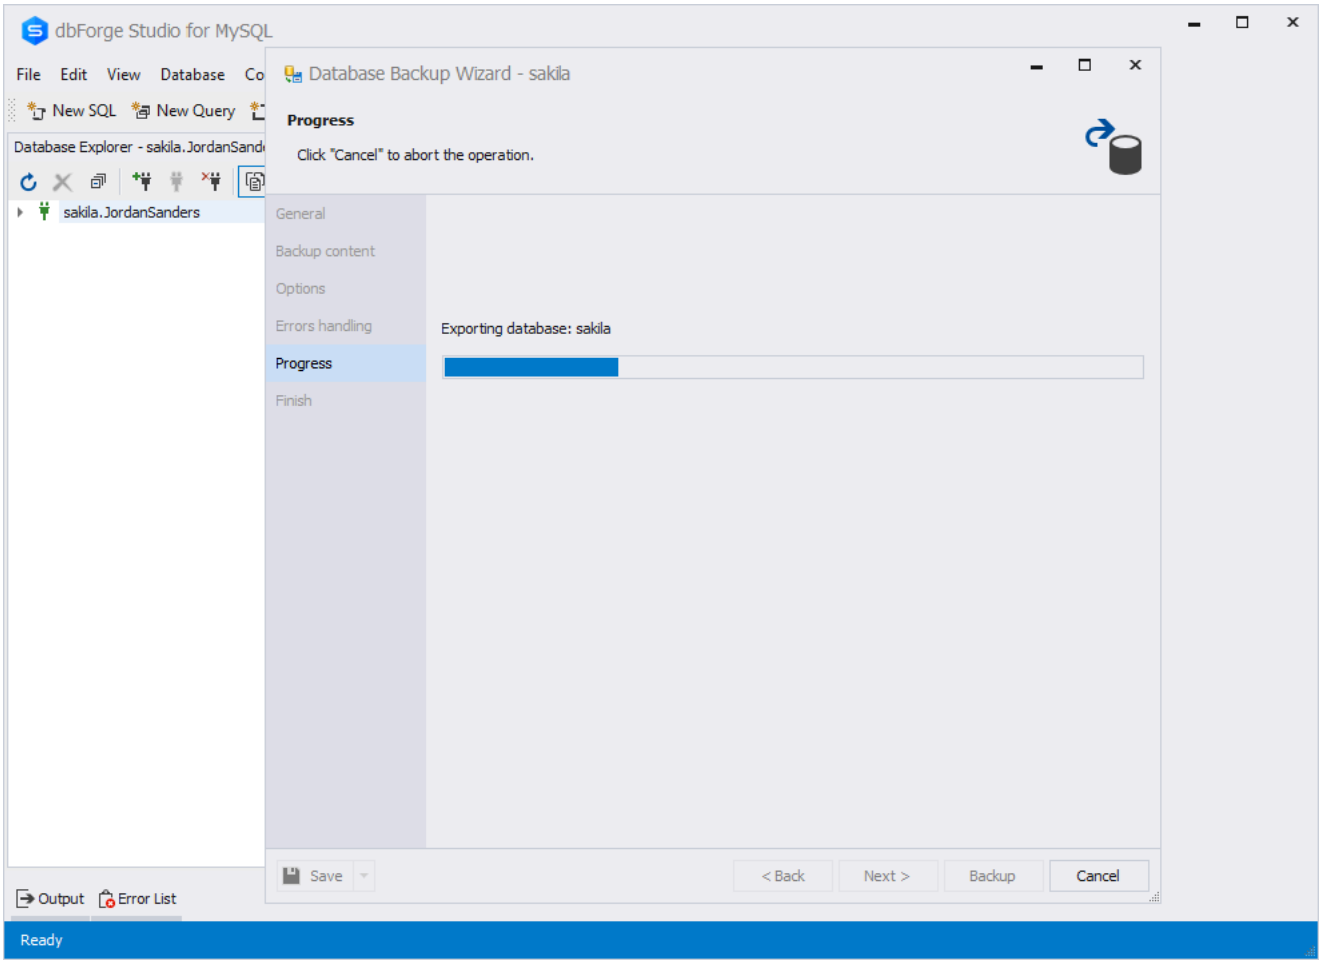
The configuration process is complete. Click Backup to launch the data backing up.

Note: It is not obligatory to go through all the pages of the Wizard. The Backup button is available no matter on which page you are. Thus, you can launch the process of backing the data up whenever you have set everything you needed.



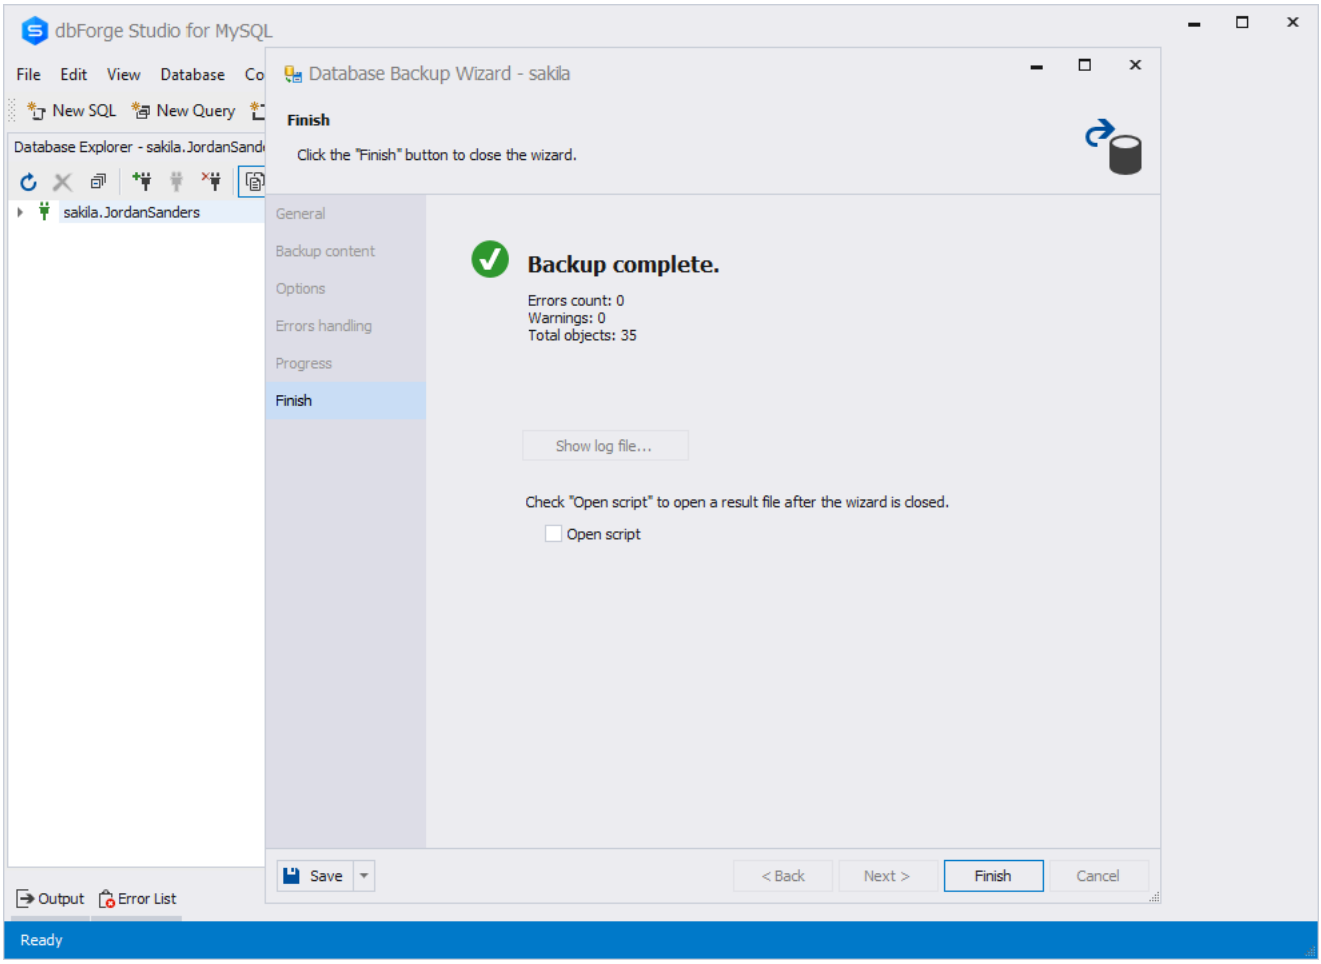
b4

After you have clicked **Backup**, dbForge Studio for MySQL starts to create a MariaDB backup.



b5

When this is done, you will see the confirmation message. Click **Finish**.



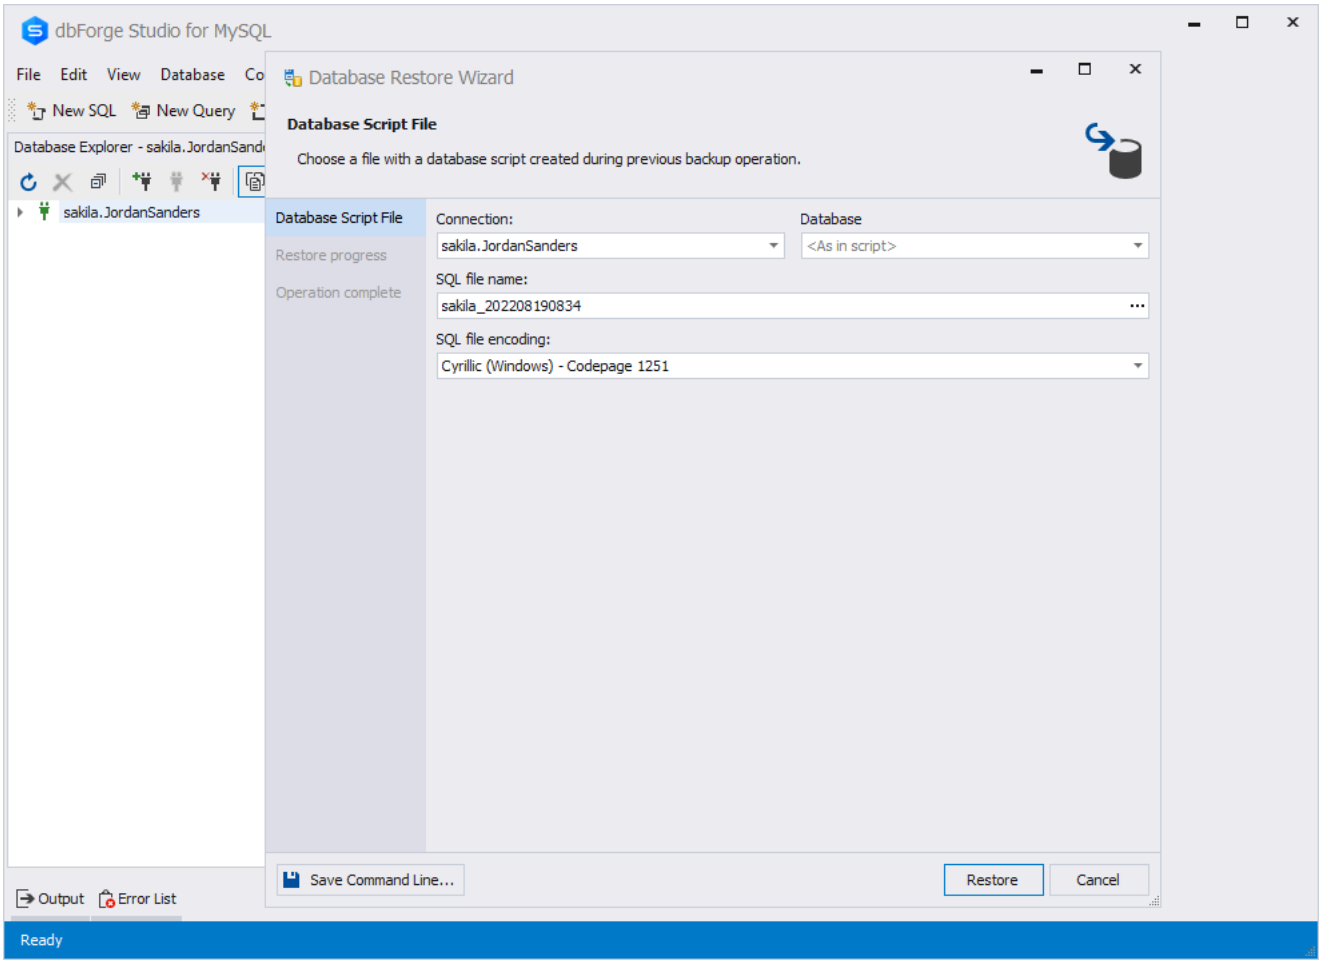
b6

Backup and restore policies suggest creating regular backups on a daily, weekly, monthly, quarterly, and yearly basis. Besides, to minimize the consequences of possible data loss, it is highly recommended make a backup before making any changes to a database, such as upgrading, modifying data, redesigning the structure, etc. Simply speaking, you always need a fresh backup to restore the most up-to-date database version.
To ensure regular backups on schedule, you can use a batch file created with the help of the Studio and **Windows Task Scheduler**, where you need to create and schedule the backup task.

Restore the backup file on MariaDB

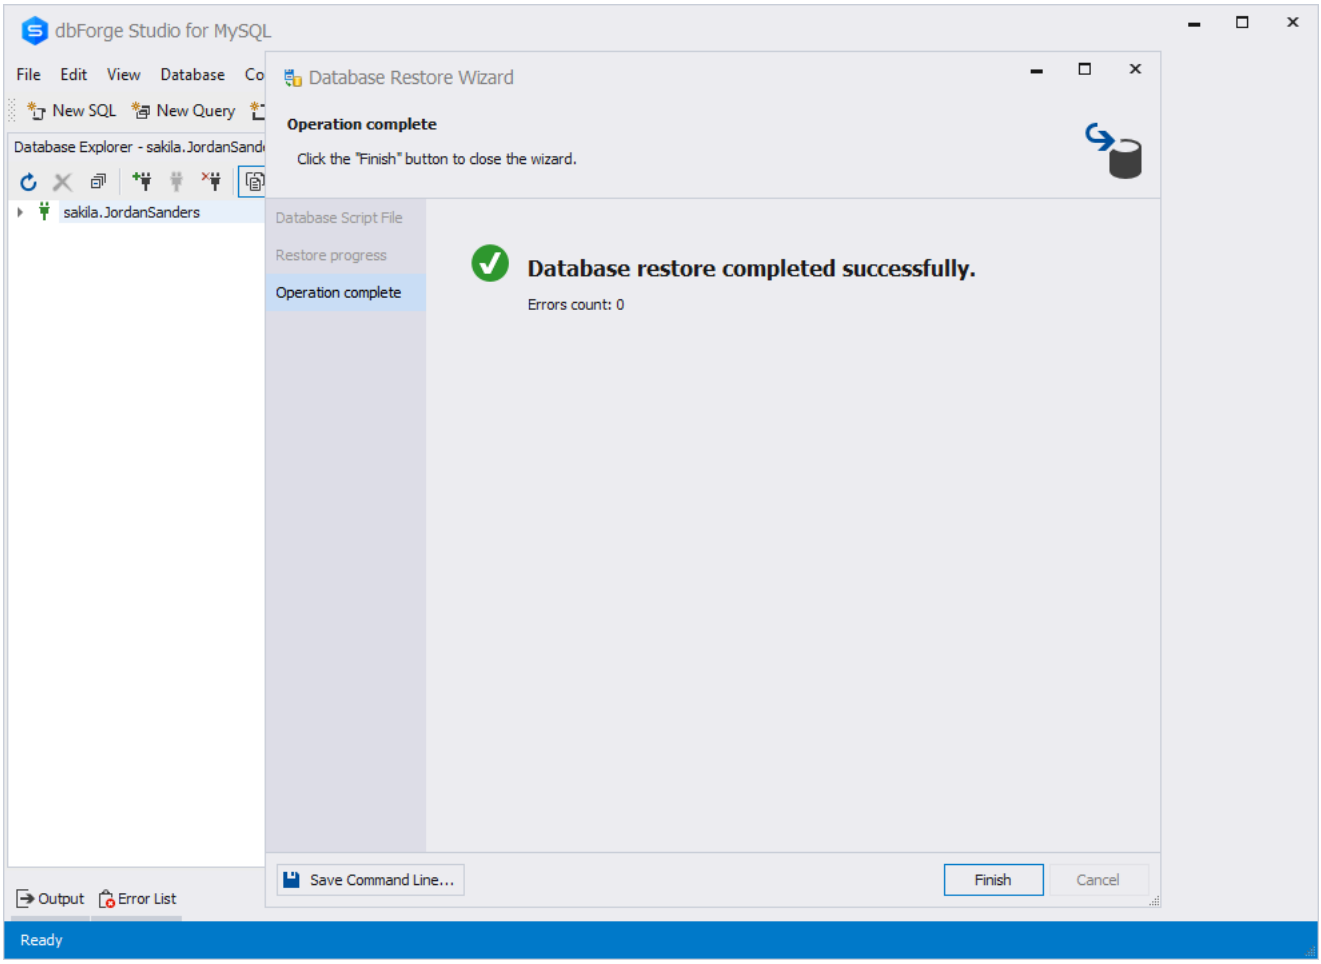
This is an even faster task, done in half as many steps.

The process of data recovery from the backup file is simple. It only takes several clicks:
Launch dbForge Studio for MySQL and go to **Database > Backup and Restore > Restore Database**. The **Database Restore Wizard** will appear.
Specify the database name, its connection parameters, and the path to the backup file you want to restore. Then click **Restore**, and the process will start immediately.



r1

When the process is complete, click **Finish**.



r2

More information about this essential feature is available on the dedicated backup and restore page – it explores the routines performed on MySQL, but they fully apply to MariaDB backups. You can use the same IDE and the same workflow.

To test-drive this and other features of the Studio (the IDE includes all the tools necessary for the development, management, and administration of databases on MariaDB), download dbForge Studio for a free 30-day trial. dbForge Studio for MySQL and MariaDB boasts truly advanced functionality that will help your teams deliver more value.

Copying Tables Between Databases and Servers

With MariaDB it's very easy to copy tables between different MariaDB databases and different MariaDB servers. This works for tables created with the Archive, Aria, CSV, InnoDB, MyISAM, MERGE, and XtraDB engines.

The normal procedures to copy a table is:

```
FLUSH TABLES db_name.table_name FOR EXPORT

# Copy the relevant files associated with the table

UNLOCK TABLES;
```

The table files can be found in datadir/databasename (you can execute `SELECT @@datadir` to find the correct directory).
When copying the files, you should copy all files with the same table_name + various extensions. For example, for an Aria table of name foo, you will have files foo.frm, foo.MAI, foo.MAD and possibly foo.TRG if you have triggers.

If one wants to distribute a table to a user that doesn't need write access to the table and one wants to minimize the storage size of the table, the recommended engine to use is Aria or MyISAM as one can pack the table with aria_pack or myisampack respectively to make it notablly smaller. MyISAM is the most portable format as it's not dependent on whether the server settings are different. Aria and InnoDB require the same block size on both servers.

Copying Tables When the MariaDB Server is Down

The following storage engines support export without `FLUSH TABLES ... FOR EXPORT`, assuming the source server is down and the receiving server is not accessing the files during the copy.

Engine	Comment
Archive	

Engine	Comment
Aria	Requires clean shutdown. Table will automatically be fixed on the receiving server if aria_chk –zerofill was not run. If aria_chk –zerofill is run, then the table is immediately usable without any delays
CSV	
MyISAM	
MERGE	.MRG files can be copied even while server is running as the file only contains a list of tables that are part of merge.

Copying Tables Live From a Running MariaDB Server

For all of the above storage engines (Archive, Aria, CSV, MyISAM and MERGE), one can copy tables even from a live server under the following circumstances:

- You have done a `FLUSH TABLES` or `FLUSH TABLE table_name` for the specific table.
- The server is not accessing the tables during the copy process.

The advantage of FLUSH TABLES table_name FOR EXPORT is that the table is read locked until UNLOCK TABLES is executed.

Warning: If you do the above live copy, you are doing this on **your own risk** as if you do something wrong, the copied table is very likely to be corrupted. The original table will of course be fine.

An Efficient Way to Give Someone Else Access to a Read Only Table

If you want to give a user access to some data in a table for the user to use in their MariaDB server, you can do the following:

First let's create the table we want to export. To speed up things, we create this without any indexes. We use `TRANSACTIONAL=0 ROW_FORMAT=DYNAMIC` for Aria to use the smallest possible row format.

```
CREATE TABLE new_table ... ENGINE=ARIA TRANSACTIONAL=0;
ALTER TABLE new_table DISABLE_KEYS;
# Fill the table with data:
INSERT INTO new_table SELECT * ...
FLUSH TABLE new_table WITH READ LOCK;

# Copy table data to some external location, like /tmp with something
# like cp /my/data/test/new_table.* /tmp/

UNLOCK TABLES;
```

Then we pack it and generate the indexes. We use a big sort buffer to speed up generating the index.

```
> ls -l /tmp/new_table.*
-rw-rw---- 1 mysql my 42396148 Sep 21 17:58 /tmp/new_table.MAD
-rw-rw---- 1 mysql my     8192 Sep 21 17:58 /tmp/new_table.MAI
-rw-rw---- 1 mysql my     1039 Sep 21 17:58 /tmp/new_table.frm
> aria_pack /tmp/new_table
Compressing /tmp/new_table.MAD: (922666 records)
- Calculating statistics
- Compressing file
46.07%
> aria_chk -rq --ignore-control-file --sort_buffer_size=1G /tmp/new_table
Recreating table '/tmp/new_table'
- check record delete-chain
- recovering (with sort) Aria-table '/tmp/new_table'
Data records: 922666
- Fixing index 1
State updated
> ls -l /tmp/new_table.*
-rw-rw---- 1 mysql my 26271608 Sep 21 17:58 /tmp/new_table.MAD
-rw-rw---- 1 mysql my 10207232 Sep 21 17:58 /tmp/new_table.MAI
-rw-rw---- 1 mysql my     1039 Sep 21 17:58 /tmp/new_table.frm
```

The procedure for MyISAM tables is identical, except that myisamchk doesn't have the `--ignore-control-file` option.

Copying InnoDB's Transportable Tablespaces

InnoDB's file-per-table tablespaces are transportable, which means that you can copy a file-per-table tablespace from one MariaDB Server to another server. See Copying Transportable Tablespaces for more information.

Importing Tables

Tables that use most storage engines are immediately usable when their files are copied to the new datadir.

However, this is not true for tables that use InnoDB. InnoDB tables have to be imported with ALTER TABLE … IMPORT TABLESPACE. See Copying Transportable Tablespaces for more information.

ALTER TABLE

Syntax

> **Note:**
>
> In the syntax, these options are the same as for the CREATE TABLE statement:
>
> - table_option
> - column_definition
> - partition_options
> - partition_definition

```
ALTER [ONLINE] [IGNORE] TABLE [IF EXISTS] tbl_name
    [WAIT n | NOWAIT]
    alter_specification [, alter_specification] ...

alter_specification:
    table_option ...
  | ADD [COLUMN] [IF NOT EXISTS] col_name column_definition
        [FIRST | AFTER col_name ]
  | ADD [COLUMN] [IF NOT EXISTS] (col_name column_definition, ...)
  | ADD {INDEX|KEY} [IF NOT EXISTS] [index_name]
        [index_type] (index_col_name,...) [index_option] ...
  | ADD [CONSTRAINT [symbol]] PRIMARY KEY [IF NOT EXISTS]
        [index_type] (index_col_name,...) [index_option] ...
  | ADD [CONSTRAINT [symbol]]
        UNIQUE [INDEX|KEY] [IF NOT EXISTS] [index_name]
        [index_type] (index_col_name,...) [index_option] ...
  | ADD FULLTEXT [INDEX|KEY] [IF NOT EXISTS [index_name]
        (index_col_name,...) [index_option] ...
  | ADD SPATIAL [INDEX|KEY] [IF NOT EXISTS [index_name]
        (index_col_name,...) [index_option] ...
  | ADD VECTOR [INDEX|KEY] [IF NOT EXISTS [index_name]
        (index_col_name,...) [index_option] ...
  | ADD [CONSTRAINT [symbol]]
        FOREIGN KEY [IF NOT EXISTS] [index_name] (index_col_name,...)
        reference_definition
  | ADD PERIOD FOR [time_period_name|SYSTEM_TIME] (start_column_name, end_column_name)
  | ALTER [COLUMN] col_name SET DEFAULT literal | (expression)
  | ALTER [COLUMN] col_name DROP DEFAULT
  | ALTER {INDEX|KEY} [IF EXISTS] index_name [NOT] IGNORED
  | CHANGE [COLUMN] [IF EXISTS] old_col_name new_col_name column_definition
        [FIRST|AFTER col_name]
  | MODIFY [COLUMN] [IF EXISTS] col_name column_definition
        [FIRST | AFTER col_name]
  | DROP [COLUMN] [IF EXISTS] col_name [RESTRICT|CASCADE]
  | DROP [CONSTRAINT] PRIMARY KEY
  | DROP {INDEX|KEY} [IF EXISTS] index_name
  | DROP FOREIGN KEY [IF EXISTS] fk_symbol
  | DROP CONSTRAINT [IF EXISTS] constraint_name
  | DISABLE KEYS
  | ENABLE KEYS
  | RENAME [TO] new_tbl_name
  | ORDER BY col_name [, col_name] ...
  | RENAME COLUMN [IF EXISTS] old_col_name TO new_col_name
  | RENAME {INDEX|KEY} old_index_name TO new_index_name
  | CONVERT TO CHARACTER SET charset_name [COLLATE collation_name]
  | [DEFAULT] CHARACTER SET [=] charset_name
  | [DEFAULT] COLLATE [=] collation_name

  | IMPORT TABLESPACE
  | ALGORITHM [=] {DEFAULT|INPLACE|COPY|NOCOPY|INSTANT}
  | LOCK [=] {DEFAULT|NONE|SHARED|EXCLUSIVE}
  | FORCE
  | partition_options
  | CONVERT TABLE normal_table TO partition_definition [{WITH | WITHOUT} VALIDATION]
  | CONVERT PARTITION partition_name TO TABLE tbl_name
  | ADD PARTITION [IF NOT EXISTS] (partition_definition)
  | DROP PARTITION [IF EXISTS] partition_names
  | TRUNCATE PARTITION partition_names
  | COALESCE PARTITION number
  | REORGANIZE PARTITION [partition_names INTO (partition_definitions)]
  | ANALYZE PARTITION partition_names
  | CHECK PARTITION partition_names
  | OPTIMIZE PARTITION partition_names
  | REBUILD PARTITION partition_names
  | REPAIR PARTITION partition_names
  | EXCHANGE PARTITION partition_name WITH TABLE tbl_name [{WITH | WITHOUT} VALIDATION]
  | REMOVE PARTITIONING
  | ADD SYSTEM VERSIONING
```

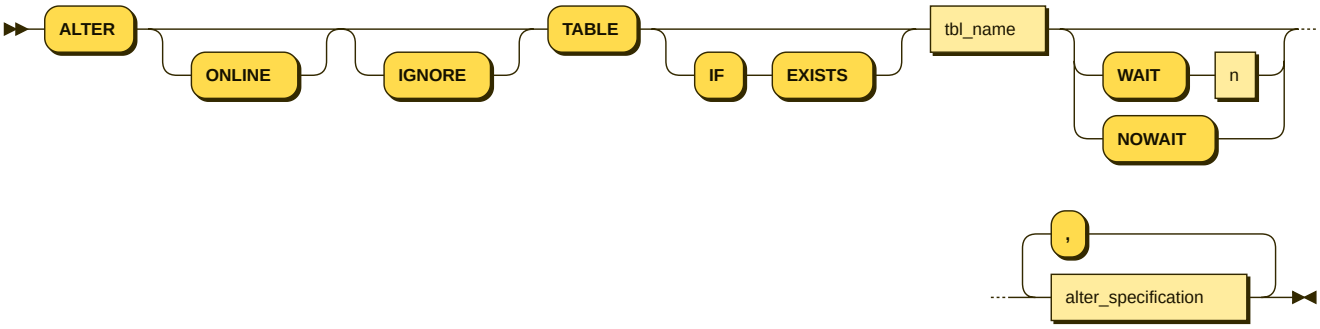
```
  | DROP SYSTEM VERSIONING

index_col_name:
    col_name [(length)] [ASC | DESC]

index_type:
    USING {BTREE | HASH | RTREE}

index_option:
    KEY_BLOCK_SIZE [=] value
  | index_type
  | WITH PARSER parser_name
  | VISIBLE
  | COMMENT 'string'
  | CLUSTERING={YES | NO}
  | { IGNORED | NOT IGNORED }
  | DISTANCE={EUCLIDEAN | COSINE}
  | M=number

  table_option [[,] table_option] ...
```



This Railroad diagram is described in the preceding BNF diagram

Description

`ALTER TABLE` enables you to change the structure of an existing table. For example, you can add or delete columns, create or destroy indexes, change the type of existing columns, or rename columns or the table itself. You can also change the comment for the table and the storage engine of the table.

If another connection is using the table, a metadata lock is active, and this statement will wait until the lock is released. This is also true for non-transactional tables.

When adding a `UNIQUE` index on a column (or a set of columns) which have duplicated values, an error will be produced and the statement will be stopped. To suppress the error and force the creation of `UNIQUE` indexes, discarding duplicates, the IGNORE option can be specified. This can be useful if a column (or a set of columns) should be UNIQUE but it contains duplicate values; however, this technique provides no control on which rows are preserved and which are deleted. Also, note that `IGNORE` is accepted but ignored in `ALTER TABLE ... EXCHANGE PARTITION` statements.

This statement can also be used to rename a table. For details see RENAME TABLE.

When an index is created, the storage engine may use a configurable buffer in the process. Incrementing the buffer speeds up the index creation. Aria and MyISAM allocate a buffer whose size is defined by aria_sort_buffer_size or myisam_sort_buffer_size, also used for REPAIR TABLE. InnoDB allocates three buffers whose size is defined by innodb_sort_buffer_size.

Privileges

Executing the `ALTER TABLE` statement generally requires at least the ALTER privilege for the table or the database. If you are renaming a table, this also requires the DROP, CREATE and INSERT privileges for the table or the database.

Online DDL

Online DDL is supported with the ALGORITHM and LOCK clauses.

See InnoDB Online DDL Overview for more information on online DDL with InnoDB.

ALTER ONLINE TABLE

`ALTER ONLINE TABLE` also works for partitioned tables.

`ALTER ONLINE TABLE ...` is equivalent to the `ALTER TABLE ... LOCK = NONE`.

See the LOCK alter specification for more information.

WAIT/NOWAIT

Set the lock wait timeout. See WAIT and NOWAIT.

IF EXISTS

The `IF EXISTS` and `IF NOT EXISTS` clauses are available for the following clauses:

```
ADD COLUMN       [IF NOT EXISTS]
ADD INDEX        [IF NOT EXISTS]
ADD FOREIGN KEY  [IF NOT EXISTS]
ADD PARTITION    [IF NOT EXISTS]
CREATE INDEX     [IF NOT EXISTS]
DROP COLUMN      [IF EXISTS]
DROP INDEX       [IF EXISTS]
DROP FOREIGN KEY [IF EXISTS]
DROP PARTITION   [IF EXISTS]
CHANGE COLUMN    [IF EXISTS]
MODIFY COLUMN    [IF EXISTS]
DROP INDEX       [IF EXISTS]
```

When `IF EXISTS` and `IF NOT EXISTS` are used in clauses, queries will not report errors when the condition is triggered for that clause. A warning with the same message text will be issued and the `ALTER` will move on to the next clause in the statement (or end if finished).

If this is directive is used after `ALTER ... TABLE`, you don't get an error if the table doesn't exist. Example:

```
CREATE TABLE t (i INT);
ALTER TABLE IF EXISTS t RENAME COLUMN IF EXISTS i TO k;
```

Column Definitions

See CREATE TABLE: Column Definitions for information about column definitions.

Index Definitions

See CREATE TABLE: Index Definitions for information about index definitions.

The CREATE INDEX and DROP INDEX statements can also be used to add or remove an index.

Character Sets and Collations

```
CONVERT TO CHARACTER SET charset_name [COLLATE collation_name]
[DEFAULT] CHARACTER SET [=] charset_name
[DEFAULT] COLLATE [=] collation_name
```

See Setting Character Sets and Collations for details on setting the character sets and collations.

Alter Specifications

Table Options

See CREATE TABLE: Table Options for information about table options.

ADD COLUMN

```
... ADD COLUMN [IF NOT EXISTS]  (col_name [column_definition](../create/create-table.md#column-definitions),...)
```

Adds a column to the table. The syntax is the same as in CREATE TABLE. If you are using `IF NOT_EXISTS` the column will not be added if it was not there already. This is very useful when doing scripts to modify tables.

The `FIRST` and `AFTER` clauses affect the physical order of columns in the datafile. Use `FIRST` to add a column in the first (leftmost) position, or `AFTER` followed by a column name to add the new column in any other position. Note that, nowadays, the physical position of a column is usually irrelevant.

See also Instant ADD COLUMN for InnoDB.

DROP COLUMN

```
... DROP COLUMN [IF EXISTS] col_name [CASCADE|RESTRICT]
```

Drops the column from the table. If you are using `IF EXISTS` you will not get an error if the column didn't exist. If the column is part of any index, the column will be dropped from them, except if you add a new column with identical name at the same time. The index will be dropped if all columns from the index were dropped. If the column was used in a view or trigger, you will get an error next time the view or trigger is accessed. Dropping a column that is part of a multi-column `UNIQUE` constraint is not permitted. For example:

```
CREATE TABLE a (
  a int,
  b int,
  primary key (a,b)
);

ALTER TABLE x DROP COLUMN a;
[42000][1072] Key column 'A' doesn't exist in table
```

The reason is that dropping column `a` would result in the new constraint that all values in column `b` be unique. In order to drop the column, an explicit `DROP PRIMARY KEY` and `ADD PRIMARY KEY` would be required.

MariaDB supports instant DROP COLUMN. DROP COLUMN of an indexed column would imply DROP INDEX (and in the case of a non-UNIQUE multi-column index, possibly ADD INDEX). These will not be allowed with ALGORITHM=INSTANT, but unlike prior versions, they can be allowed with ALGORITHM=NOCOPY

`RESTRICT` and `CASCADE` are allowed to make porting from other database systems easier. In MariaDB, they do nothing.

MODIFY COLUMN

Allows you to modify the type of a column. The column will be at the same place as the original column and all indexes on the column will be kept. Note that when modifying column, you should specify all attributes for the new column.

```
CREATE TABLE t1 (a INT UNSIGNED AUTO_INCREMENT, PRIMARY KEY((a));
ALTER TABLE t1 MODIFY a BIGINT UNSIGNED AUTO_INCREMENT;
```

CHANGE COLUMN

Works like `MODIFY COLUMN` except that you can also change the name of the column. The column will be at the same place as the original column and all index on the column will be kept.

```
CREATE TABLE t1 (a INT UNSIGNED AUTO_INCREMENT, PRIMARY KEY(a));
ALTER TABLE t1 CHANGE a b BIGINT UNSIGNED AUTO_INCREMENT;
```

ALTER COLUMN

This lets you change column options.

```
CREATE TABLE t1 (a INT UNSIGNED AUTO_INCREMENT, b varchar(50), PRIMARY KEY(a));
ALTER TABLE t1 ALTER b SET DEFAULT 'hello';
```

RENAME INDEX/KEY

CURRENT

You can rename an index using the `RENAME INDEX` (or `RENAME KEY`) syntax:

```
ALTER TABLE t1 RENAME INDEX i_old TO i_new;
```

< 10.5.3

`RENAME INDEX/KEY` is not available.

RENAME COLUMN

CURRENT

You can rename a column using the `RENAME COLUMN` syntax:

```
ALTER TABLE t1 RENAME COLUMN c_old TO c_new;
```

< 10.5.3

`RENAME COLUMN` is not available.

ADD PRIMARY KEY

Adds a primary key. For `PRIMARY KEY` indexes, you can specify a name for the index, but it is silently ignored, and the name of the index is always `PRIMARY`. See Getting Started with Indexes: Primary Key for more information.

DROP PRIMARY KEY

Drops a primary key. For `PRIMARY KEY` indexes, you can specify a name for the index, but it is silently ignored, and the name of the index is always `PRIMARY`. See Getting Started with Indexes: Primary Key for more information.

ADD FOREIGN KEY

Adds a foreign key. For `FOREIGN KEY` indexes, a reference definition must be provided. For `FOREIGN KEY` indexes, you can specify a name for the constraint, using the `CONSTRAINT` keyword. That name will be used in error messages.

First, you have to specify the name of the target (parent) table and a column or a column list which must be indexed and whose values must match to the foreign key's values. The `MATCH` clause is accepted to improve the

compatibility with other DBMS's, but has no meaning in MariaDB. The `ON DELETE` and `ON UPDATE` clauses specify what must be done when a `DELETE` (or a `REPLACE`) statements attempts to delete a referenced row from the parent table, and when an `UPDATE` statement attempts to modify the referenced foreign key columns in a parent table row, respectively. The following options are allowed:

- `RESTRICT`: The delete/update operation is not performed. The statement terminates with a 1451 error (SQLSTATE '2300').
- `NO ACTION`: Synonym for `RESTRICT`.
- `CASCADE`: The delete/update operation is performed in both tables.
- `SET NULL`: The update or delete goes ahead in the parent table, and the corresponding foreign key fields in the child table are set to `NULL`. (They must not be defined as `NOT NULL` for this to succeed).
- `SET DEFAULT`: This option is implemented only for the legacy PBXT storage engine, which is disabled by default and no longer maintained. It sets the child table's foreign key fields to their `DEFAULT` values when the referenced parent table key entries are updated or deleted.

If either clause is omitted, the default behavior for the omitted clause is `RESTRICT`.

See Foreign Keys for more information.

DROP FOREIGN KEY

Drops a foreign key. See Foreign Keys for more information.

ADD INDEX

Adds a plain index. Plain indexes are regular indexes that are not unique, and are not acting as a primary key or a foreign key. They are also not the "specialized" `FULLTEXT` or `SPATIAL` indexes. For limits on InnoDB indexes, see InnoDB Limitations. See Getting Started with Indexes: Plain Indexes for more information.

DROP INDEX

Drops a plain index. Plain indexes are regular indexes that are not unique, and are not acting as a primary key or a foreign key. They are also not the "specialized" `FULLTEXT` or `SPATIAL` indexes. See Getting Started with Indexes: Plain Indexes for more information.

ADD UNIQUE INDEX

Adds a unique index. The `UNIQUE` keyword means that the index will not accept duplicated values, except for NULLs. An error will raise if you try to insert duplicate values in a UNIQUE index. For `UNIQUE` indexes, you can specify a name for the constraint, using the `CONSTRAINT` keyword. That name will be used in error messages. See Getting Started with Indexes: Unique Index for more information.

DROP UNIQUE INDEX

Drops a unique index. The `UNIQUE` keyword means that the index will not accept duplicated values, except for NULLs. An error will raise if you try to insert duplicate values in a UNIQUE index. For `UNIQUE` indexes, you can specify a name for the constraint, using the `CONSTRAINT` keyword. That name will be used in error messages. See Getting Started with Indexes: Unique Index for more information.

ADD FULLTEXT INDEX

Adds a `FULLTEXT` index. See Full-Text Indexes for more information.

DROP FULLTEXT INDEX

Drops a `FULLTEXT` index. See Full-Text Indexes for more information.

ADD SPATIAL INDEX

Adds a SPATIAL index. See SPATIAL INDEX for more information.

DROP SPATIAL INDEX

Drops a SPATIAL index. See SPATIAL INDEX for more information.

ENABLE/ DISABLE KEYS

`DISABLE KEYS` disables all non unique keys for the table for storage engines that support this (at least MyISAM and Aria). This can be used to speed up inserts into empty tables. `ENABLE KEYS` enables all disabled keys.

RENAME TO

Renames a table. See also RENAME TABLE.

ADD CONSTRAINT

Modifies the table adding a constraint on a particular column or columns.

```
ALTER TABLE table_name
ADD CONSTRAINT [constraint_name] CHECK(expression);
```

Before a row is inserted or updated, all constraints are evaluated in the order they are defined. If any constraint fails, then the row will not be updated. One can use most deterministic functions in a constraint, including UDF's.

```
CREATE TABLE account_ledger (
    id INT PRIMARY KEY AUTO_INCREMENT,
    transaction_name VARCHAR(100),
    credit_account VARCHAR(100),
    credit_amount INT,
    debit_account VARCHAR(100),
    debit_amount INT);

ALTER TABLE account_ledger
ADD CONSTRAINT is_balanced
    CHECK((debit_amount + credit_amount) = 0);
```

The `constraint_name` is optional. If you don't provide one in the `ALTER TABLE` statement, MariaDB auto-generates a name for you. This is done so that you can remove it later using DROP CONSTRAINT clause.

You can disable all constraint expression checks by setting the variable check_constraint_checks to `OFF`. You may find this useful when loading a table that violates some constraints that you want to later find and fix in SQL.

To view constraints on a table, query information_schema.TABLE_CONSTRAINTS:

```
SELECT CONSTRAINT_NAME, TABLE_NAME, CONSTRAINT_TYPE
FROM information_schema.TABLE_CONSTRAINTS
WHERE TABLE_NAME = 'account_ledger';

+-----------------+----------------+-----------------+
| CONSTRAINT_NAME | TABLE_NAME     | CONSTRAINT_TYPE |
+-----------------+----------------+-----------------+
| is_balanced     | account_ledger | CHECK           |
+-----------------+----------------+-----------------+
```

DROP CONSTRAINT

`DROP CONSTRAINT` for `UNIQUE` and `FOREIGN KEY` constraints and `DROP CONSTRAINT` for `CHECK` constraints were introduced in an earlier version of MariaDB.

Modifies the table, removing the given constraint.

```
ALTER TABLE table_name
DROP CONSTRAINT constraint_name;
```

When you add a constraint to a table, whether through a CREATE TABLE or ALTER TABLE…ADD CONSTRAINT statement, you can either set a `constraint_name` yourself, or allow MariaDB to auto-generate one for you. To view constraints on a table, query information_schema.TABLE_CONSTRAINTS. For instance,

```
CREATE TABLE t (
   a INT,
   b INT,
   c INT,
   CONSTRAINT CHECK(a > b),
   CONSTRAINT check_equals CHECK(a = c));

SELECT CONSTRAINT_NAME, TABLE_NAME, CONSTRAINT_TYPE
FROM information_schema.TABLE_CONSTRAINTS
WHERE TABLE_NAME = 't';

+-----------------+----------------+-----------------+
| CONSTRAINT_NAME | TABLE_NAME     | CONSTRAINT_TYPE |
+-----------------+----------------+-----------------+
| check_equals    | t              | CHECK           |
| CONSTRAINT_1    | t              | CHECK           |
+-----------------+----------------+-----------------+
```

To remove a constraint from the table, issue an `ALTER TABLE...DROP CONSTRAINT` statement:

```
ALTER TABLE t DROP CONSTRAINT is_unique;
```

ADD SYSTEM VERSIONING

Adds system versioning. See System-versioned tables.

DROP SYSTEM VERSIONING

Drops system versioning. See System-versioned tables.

ADD PERIOD FOR

See System-versioned tables, Application-time-period tables or Bitemporal Tables.

FORCE

`ALTER TABLE ... FORCE` forces MariaDB to rebuild the table.

```
ALTER TABLE tab_name FORCE;
```

With InnoDB, the table rebuild only reclaims unused space (i.e. the space previously used for deleted rows) if the innodb_file_per_table system variable is set to `ON` (the default). If the system variable is `OFF`, the space will not be reclaimed, but it will be reused for new data that's later added.

The rebuild may fail if conditions are violated due to a change in the sql_mode. For example:

```
CREATE OR REPLACE TABLE x (d DATE DEFAULT '0000-00-00');

SET SQL_MODE='NO_ZERO_DATE';

ALTER TABLE x FORCE;
ERROR 1067 (42000): Invalid default value for 'd'
```

Partitions

ADD PARTITION

See Partitioning Overview: Adding Partitions for details.

ANALYZE PARTITION

See Partitioning Overview: Analyzing Partitions for details.

CHECK PARTITION

See Partitioning Overview: Checking Partitions for details.

COALESCE PARTITION

Reduces the number of HASH or KEY partitions in a table. See Partitioning Overview: Coalescing Partitions.

CONVERT PARTITION / TABLE

CURRENT

`CONVERT PARTITION` can be used to remove a partition from a table and make this an ordinary table. For example:

```
ALTER TABLE partitioned_table CONVERT PARTITION part1 TO TABLE normal_table;
```

`CONVERT TABLE` will take an existing table and move this to another table as its own partition with a specified partition definition. For example the following moves `normal_table` to a partition of `partitioned_table` with a definition that its values, based on the `PARTITION BY` of the `partitioned_table`, are less than 12345.

```
ALTER TABLE partitioned_table CONVERT TABLE normal_table
  TO PARTITION part1 VALUES LESS THAN (12345);
```

The optional `[{WITH | WITHOUT} VALIDATION]` is permitted.

See Partitioning Overview: Converting Partitions to/from Tables for more details.

< 11.4

`CONVERT PARTITION` can be used to remove a partition from a table and make this an ordinary table. For example:

```
ALTER TABLE partitioned_table CONVERT PARTITION part1 TO TABLE normal_table;
```

`CONVERT TABLE` will take an existing table and move this to another table as its own partition with a specified partition definition. For example the following moves `normal_table` to a partition of `partitioned_table` with a definition that its values, based on the `PARTITION BY` of the `partitioned_table`, are less than 12345.

```
ALTER TABLE partitioned_table CONVERT TABLE normal_table
  TO PARTITION part1 VALUES LESS THAN (12345);
```

The optional clause `[{WITH | WITHOUT} VALIDATION]` is not available.

See Partitioning Overview: Converting Partitions to/from Tables for more details.

< 10.7

`CONVERT PARTITION` and `CONVERT TABLE` are not available.

DROP PARTITION

Used to drop specific partitions (and discard all data within the specified partitions) for RANGE and LIST partitions. See Partitioning Overview: Dropping Partitions.

EXCHANGE PARTITION

> #### CURRENT
>
> This clause is used to exchange the contents of a partition with another table. This is performed by swapping the tablespaces of the partition with the other table.

OPTIMIZE PARTITION

See Partitioning Overview: Optimizing Partitions for details.

REMOVE PARTITIONING

See Partitioning Overview: Removing Partitioning.

REORGANIZE PARTITION

See Partitioning Overview: Reorganizing Partitions.

TRUNCATE PARTITION

See Partitioning Overview: Truncating Partitions.

DISCARD TABLESPACE

This is used to discard an InnoDB table's tablespace.

See copying InnoDB's transportable tablespaces for more information.

IMPORT TABLESPACE

This is used to import an InnoDB table's tablespace. The tablespace should have been copied from its original server after executing FLUSH TABLES FOR EXPORT.

See copying InnoDB's transportable tablespaces for more information.

`ALTER TABLE ... IMPORT` only applies to InnoDB tables. Most other popular storage engines, such as Aria and MyISAM, will recognize their data files as soon as they've been placed in the proper directory under the datadir, and no special DDL is required to import them.

ALGORITHM

The `ALTER TABLE` statement supports the `ALGORITHM` clause. This clause is one of the clauses that is used to implement online DDL. `ALTER TABLE` supports several different algorithms. An algorithm can be explicitly chosen for an `ALTER TABLE` operation by setting the `ALGORITHM` clause. The supported values are:

- `ALGORITHM=DEFAULT` - This implies the default behavior for the specific statement, such as if no `ALGORITHM` clause is specified.
- `ALGORITHM=COPY`
- `ALGORITHM=INPLACE`
- `ALGORITHM=NOCOPY`
- `ALGORITHM=INSTANT`

See InnoDB Online DDL Overview: ALGORITHM for information on how the `ALGORITHM` clause affects InnoDB.

ALGORITHM=DEFAULT

The default behavior, which occurs if `ALGORITHM=DEFAULT` is specified, or if `ALGORITHM` is not specified at all, usually only makes a copy if the operation doesn't support being done in-place at all. In this case, the most efficient available algorithm will usually be used.

The old_alter_table system variable is deprecated. Instead, the alter_algorithm system variable defines the default algorithm for `ALTER TABLE` operations. This was removed in MariaDB 11.5 for the following reasons:

- alter_algorithm was introduced as a replacement for the old_alter_table that was used to force the usage of the original alter table algorithm (copy) in cases where the new alter algorithm did not work. The new option was added as a way to force the usage of a specific algorithm when it should instead have made it possible to disable algorithms that would not work for some reason.
- alter_algorithm introduced some cases where ALTER TABLE would not work without specifying the ALGORITHM=XXX option together with ALTER TABLE.
- Having different values of alter_algorithm on the primary and replica could cause replicas to stop unexpectedly.
- ALTER TABLE FORCE, as used by mariadb-upgrade, would not always work if alter_algorithm was set for the server.
- As part of MDEV-33449 "improving repair of tables" it became clear that alter-algorithm made it harder to provide a better and more consistent ALTER TABLE FORCE and REPAIR TABLE, and it would be better to remove it.

ALGORITHM=COPY

`ALGORITHM=COPY` is the name for the original `ALTER TABLE` algorithm from early MariaDB versions.

When `ALGORITHM=COPY` is set, MariaDB essentially does the following operations:

```
-- Create a temporary table with the new definition
CREATE TEMPORARY TABLE tmp_tab (
...
);

-- Copy the data from the original table
INSERT INTO tmp_tab
   SELECT * FROM original_tab;

-- Drop the original table
DROP TABLE original_tab;

-- Rename the temporary table, so that it replaces the original one
RENAME TABLE tmp_tab TO original_tab;
```

This algorithm is very inefficient, but it is generic, so it works for all storage engines.

If `ALGORITHM=COPY` is specified, then the copy algorithm will be used even if it is not necessary. This can result in a lengthy table copy. If multiple `ALTER TABLE` operations are required that each require the table to be rebuilt, then it is best to specify all operations in a single `ALTER TABLE` statement, so that the table is only rebuilt once.

> **CURRENT**
>
> `ALTER TABLE` can perform most operations with `ALGORITHM=COPY`, `LOCK=NONE`. See LOCK=NONE.
>
> **< 11.2**
>
> `ALTER TABLE` cannot perform operations with `ALGORITHM=COPY`, `LOCK=NONE`.

ALGORITHM=INPLACE

`ALGORITHM=COPY` can be incredibly slow, because the whole table has to be copied and rebuilt. `ALGORITHM=INPLACE` was introduced as a way to avoid this by performing operations in-place and avoiding the table copy and rebuild, when possible.

When `ALGORITHM=INPLACE` is set, the underlying storage engine uses optimizations to perform the operation while avoiding the table copy and rebuild. However, `INPLACE` is a bit of a misnomer, since some operations may still require the table to be rebuilt for some storage engines. Regardless, several operations can be performed without a full copy of the table for some storage engines.

A more accurate name would have been `ALGORITHM=ENGINE`, where `ENGINE` refers to an "engine-specific" algorithm.

If an `ALTER TABLE` operation supports `ALGORITHM=INPLACE`, it can be performed using optimizations by the underlying storage engine, but it may rebuilt.

See InnoDB Online DDL Operations with ALGORITHM=INPLACE for more.

ALGORITHM=NOCOPY

`ALGORITHM=INPLACE` can sometimes be surprisingly slow in instances where it has to rebuild the clustered index, because when the clustered index has to be rebuilt, the whole table has to be rebuilt. `ALGORITHM=NOCOPY` was introduced as a way to avoid this.

If an `ALTER TABLE` operation supports `ALGORITHM=NOCOPY`, then it can be performed without rebuilding the clustered index.

If `ALGORITHM=NOCOPY` is specified for an `ALTER TABLE` operation that does not support `ALGORITHM=NOCOPY`, then an error will be raised. In this case, raising an error is preferable, if the alternative is for the operation to rebuild the clustered index, and perform unexpectedly slowly.

See InnoDB Online DDL Operations with ALGORITHM=NOCOPY for more.

ALGORITHM=INSTANT

`ALGORITHM=INPLACE` can sometimes be surprisingly slow in instances where it has to modify data files. `ALGORITHM=INSTANT` was introduced as a way to avoid this.

If an `ALTER TABLE` operation supports `ALGORITHM=INSTANT`, then it can be performed without modifying any data files.

If `ALGORITHM=INSTANT` is specified for an `ALTER TABLE` operation that does not support `ALGORITHM=INSTANT`, then an error will be raised. In this case, raising an error is preferable, if the alternative is for the operation to modify data files, and perform unexpectedly slowly.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT for more.

LOCK

The `ALTER TABLE` statement supports the `LOCK` clause. This clause is one of the clauses that is used to implement online DDL. `ALTER TABLE` supports several different locking strategies. A locking strategy can be explicitly chosen for an `ALTER TABLE` operation by setting the `LOCK` clause. The supported values are:

DEFAULT

Acquire the least restrictive lock on the table that is supported for the specific operation. Permit the maximum amount of concurrency that is supported for the specific operation.

NONE

Acquire no lock on the table. Permit **all** concurrent DML. If this locking strategy is not permitted for an operation, then an error is raised. From MariaDB 11.2, `ALTER TABLE` can do most operations with `ALGORITHM=COPY, LOCK=NONE`, that is, in most cases, unless the algorithm and lock level are explicitly specified, `ALTER TABLE` will be performed using the `COPY` algorithm while simultaneously allowing concurrent DML statements on the altered table. If this is not desired, one can explicitly specify a different lock level or set old_mode to LOCK_ALTER_TABLE_COPY that will make `ALGORITHM=COPY` use `LOCK=SHARED` by default (but still allowing `LOCK=NONE` to be specified explicitly).

SHARED

Acquire a read lock on the table. Permit **read-only** concurrent DML. If this locking strategy is not permitted for an operation, then an error is raised.

EXCLUSIVE

Acquire a write lock on the table. Do **not** permit concurrent DML.

Different storage engines support different locking strategies for different operations. If a specific locking strategy is chosen for an `ALTER TABLE` operation, and that table's storage engine does not support that locking strategy for that specific operation, then an error will be raised.

If the `LOCK` clause is not explicitly set, then the operation uses `LOCK=DEFAULT`.

ALTER ONLINE TABLE is equivalent to `LOCK=NONE`. Therefore, the ALTER ONLINE TABLE statement can be used to ensure that your `ALTER TABLE` operation allows all concurrent DML.

See InnoDB Online DDL Overview: LOCK for information on how the `LOCK` clause affects InnoDB.

Index Options

See CREATE TABLE page for meaning of the index options.

Progress Reporting

MariaDB provides progress reporting for `ALTER TABLE` statement for clients that support the new progress reporting protocol. For example, if you were using the mariadb client, then the progress report might look like this::

```
ALTER TABLE test ENGINE=Aria;
Stage: 1 of 2 'copy to tmp table'    46% of stage
```

The progress report is also shown in the output of the SHOW PROCESSLIST statement and in the contents of the information_schema.PROCESSLIST table.

See Progress Reporting for more information.

Aborting ALTER TABLE Operations

If an `ALTER TABLE` operation is being performed and the connection is killed, the changes will be rolled back in a controlled manner. The rollback can be a slow operation as the time it takes is relative to how far the operation has progressed.

Aborting `ALTER TABLE ... ALGORITHM=COPY` was made faster by removing excessive undo logging (MDEV-11415). This significantly shortened the time it takes to abort a running ALTER TABLE operation, compared with earlier releases.

Atomic ALTER TABLE

> **CURRENT**
>
> `ALTER TABLE` is atomic for most engines, including InnoDB, MyRocks, MyISAM and Aria (MDEV-25180). This means that if there is a crash (server down or power outage) during an `ALTER TABLE` operation, after recovery, either the old table and associated triggers and status will be intact, or the new table will be active. In older MariaDB versions one could get leftover #sql-alter..', '#sql-backup..' or 'table_name.frm˝' files if the system crashed during the `ALTER TABLE` operation.
>
> See Atomic DDL for more information.
>
> **< 10.6**
>
> Atomic `ALTER TABLE` is not available.

Replication

> **CURRENT**
>
> `ALTER TABLE` got fully executed on the primary first, and only then was it replicated and started executing on replicas. An option was added to replicate sooner and begin executing on replicas, directly when it *starts* executing on the primary, not when it *finishes*. This way the replication lag caused by a heavy `ALTER TABLE` can be completely eliminated (MDEV-11675).
>
> **< 10.8**
>
> The binlog_alter_two_phase option is not available.

Examples

Adding a new column:

```
ALTER TABLE t1 ADD x INT;
```

Dropping a column:

```
ALTER TABLE t1 DROP x;
```

Modifying the type of a column:

```
ALTER TABLE t1 MODIFY x bigint unsigned;
```

Changing the name and type of a column:

```
ALTER TABLE t1 CHANGE a b bigint unsigned auto_increment;
```

Combining multiple clauses in a single ALTER TABLE statement, separated by commas:

```
ALTER TABLE t1 DROP x, ADD x2 INT,  CHANGE y y2 INT;
```

Changing the storage engine and adding a comment:

```
ALTER TABLE t1
  ENGINE = InnoDB
  COMMENT = 'First of three tables containing usage info';
```

Rebuilding the table (the previous example will also rebuild the table if it was already InnoDB):

```
ALTER TABLE t1 FORCE;
```

Dropping an index:

```
ALTER TABLE rooms DROP INDEX u;
```

Adding a unique index:

```
ALTER TABLE rooms ADD UNIQUE INDEX u(room_number);
```

Adding a primary key for an application-time period table with a WITHOUT OVERLAPS constraint:

```
ALTER TABLE rooms ADD PRIMARY KEY(room_number, p WITHOUT OVERLAPS);
```

CURRENT

An `ALTER` query can be replicated faster with this statement, which must be run before the `ALTER` statement:

```
SET @@SESSION.binlog_alter_two_phase = TRUE;
```

Binlog would contain two event groups, of which the first one gets delivered to replicas before ALTER is taken to actual execution on the primary:

```
| master-bin.000001 | 495 | Gtid              |         1 |         537 | GTID 0-1-2 START ALTER
|
| master-bin.000001 | 537 | Query             |         1 |         655 | use `test`; alter table t add
column b int, algorithm=inplace |
| master-bin.000001 | 655 | Gtid              |         1 |         700 | GTID 0-1-3 COMMIT ALTER id=2
|
| master-bin.000001 | 700 | Query             |         1 |
```

< 10.8.1

This statement is not available:

```
SET @@SESSION.binlog_alter_two_phase = true;
```

CREATE TABLE

Syntax

```
CREATE [OR REPLACE] [TEMPORARY] TABLE [IF NOT EXISTS] tbl_name
    (create_definition,...) [table_options    ]... [partition_options]
CREATE [OR REPLACE] [TEMPORARY] TABLE [IF NOT EXISTS] tbl_name
    [(create_definition,...)] [table_options   ]... [partition_options]
    select_statement
CREATE [OR REPLACE] [TEMPORARY] TABLE [IF NOT EXISTS] tbl_name
   { LIKE old_table_name | (LIKE old_table_name) }

select_statement:
    [IGNORE | REPLACE] [AS] SELECT ...   (Some legal select statement)
```

Description

Use the `CREATE TABLE` statement to create a table with the given name.

In its most basic form, the `CREATE TABLE` statement provides a table name followed by a list of columns, indexes, and constraints. By default, the table is created in the default database. Specify a database with `db_name.tbl_name`. If you quote the table name, you must quote the database name and table name separately as `` `db_name`.`tbl_name` ``. This is particularly useful for CREATE TABLE ... SELECT, because it allows creating a table in a database that contains data from other databases. See Identifier Qualifiers.

If a table with the same name exists, error 1050 results. Use IF NOT EXISTS to suppress this error and issue a note instead. Use SHOW WARNINGS to see notes.

The `CREATE TABLE` statement automatically commits the current transaction, except when using the TEMPORARY keyword.

For valid identifiers to use as table names, see Identifier Names.

> **Note:**
>
> If the `default_storage_engine` is set to `ColumnStore`, it needs to be set on all UMs. Otherwise, when the tables using the default engine are replicated across UMs, they will use the wrong engine. You should therefore not use this option as a session variable with ColumnStore.

Microsecond precision can be between 0-6. If no precision is specified, it is assumed to be 0, for backward compatibility reasons.

Privileges

Executing the `CREATE TABLE` statement requires the CREATE privilege for the table or the database.

CREATE OR REPLACE

If the `OR REPLACE` clause is used and the table already exists, then instead of returning an error, the server will drop the existing table and replace it with the newly defined table.

This syntax was originally added to make replication more robust if it has to rollback and repeat statements such as `CREATE ... SELECT` on replicas.

```
CREATE OR REPLACE TABLE table_name (a INT);
```

is basically the same as:

```
DROP TABLE IF EXISTS TABLE_NAME;
CREATE TABLE TABLE_NAME (a INT);
```

with the following exceptions:

- If `table_name` was locked with LOCK TABLES, it will continue to be locked after the statement.
- Temporary tables are only dropped if the `TEMPORARY` keyword was used. (With DROP TABLE, temporary tables are preferred to be dropped before normal tables).

Things to be Aware of With CREATE OR REPLACE

- The table is dropped first (if it existed), and after that, the `CREATE` is done. Because of this, if the `CREATE` fails, then the table will not exist anymore after the statement. If the table was used with `LOCK TABLES`, it will be unlocked.
- One can't use `OR REPLACE` together with `IF EXISTS`.
- Replicas will, by default, use `CREATE OR REPLACE` when replicating `CREATE` statements that don't use `IF EXISTS`. This can be changed by setting the variable slave-ddl-exec-mode to `STRICT`.

CREATE TABLE IF NOT EXISTS

If the `IF NOT EXISTS` clause is used, then the table will only be created if a table with the same name does not already exist. If the table already exists, then a warning will be triggered by default.

CREATE TEMPORARY TABLE

Use the `TEMPORARY` keyword to create a temporary table that is only available to the current session. Temporary tables are dropped when the session ends. Temporary table names are specific to the session. They will not conflict with other temporary tables from other sessions, even if they share the same name. They will shadow names of non-temporary tables or views, if they are identical. A temporary table can have the same name as a non-temporary table, which is located in the same database. In that case, their name will reference the temporary table when used in SQL statements. You must have the CREATE TEMPORARY TABLES privilege on the database to create temporary tables. If no storage engine is specified, the default_tmp_storage_engine setting will determine the engine.

> **CURRENT**
>
> ROCKSDB temporary tables cannot be created by setting the default_tmp_storage_engine system variable or using `CREATE TEMPORARY TABLE LIKE`. If you try, an error is returned. Explicitly creating a temporary table with `ENGINE=ROCKSDB` has never been permitted.
>
> **< 10.7**
>
> ROCKSDB temporary tables cannot be created by setting the default_tmp_storage_engine system variable, or using `CREATE TEMPORARY TABLE LIKE`. They can be specified, but fail silently, and a `MyISAM` table is created instead. Explicitly creating a temporary table with `ENGINE=ROCKSDB` has never been permitted.

Replicating temporary tables

> **CURRENT**
>
> By default, temporary tables are only created on the replica if the primary is using the STATEMENT binary log format.
>
> The new deterministic rules for logging of temporary tables are:

- The `STATEMENT` binlog format is used. The user can change this behavior by setting create_tmp_table_binlog_formats to `MIXED`, `STATEMENT` in which case the create is logged in statement format also in `MIXED` mode (as before).
- Changes to temporary tables are only binlogged if and only if the CREATE was logged. The logging happens under `STATEMENT` or `MIXED`. If binlog_format=ROW, temporary table changes are not binlogged. A temporary table that is changed under ROW is marked as 'not up to date in binlog' and no future row changes are logged. Any usage of this temporary table will force row logging of other tables in any future statements using the temporary table to be row logged.
- `DROP TEMPORARY` is binlogged only if the `CREATE` was binlogged.

< 12.0.1

In some contexts, temporary tables on the primary and replica can become inconsistent.
One example is if a temporary table is updated with the value of a non deterministic function like UUID(), in which the change is never sent to the replica.

In some other contexts, while using `MIXED` mode, all changes will be logged in `ROW` mode while the user has any active temporary tables, even if the temporary tables are not used in the query. This depends on in which format some previous independent commands were logged.

There are many other pitfalls with logging temporary table to the replica.

CREATE TABLE ... LIKE

Use the `LIKE` clause instead of a full table definition to create an empty table with the same definition as another table, including columns, indexes, and table options. Foreign key definitions, as well as any DATA DIRECTORY or INDEX DIRECTORY table options specified on the original table, will not be created.

`LIKE` does not preserve the `TEMPORARY` status of the original table. To make the new table `TEMPORARY` as well, use `CREATE TEMPORARY TABLE ... LIKE`.

`LIKE` does not work with views, only base tables. Attempting to use it on a view will result in an error:

```
CREATE VIEW v (mycol) AS SELECT 'abc';

CREATE TABLE v2 LIKE v;
ERROR 1347 (HY000): 'test.v' is not of type 'BASE TABLE'
```

The same version of the table storage format as found in the original table is used for the new table.

`CREATE TABLE ... LIKE` performs the same checks as `CREATE TABLE`. So a statement may fail if a change in the SQL_MODE renders it invalid. For example:

```
CREATE OR REPLACE TABLE x (d DATE DEFAULT '0000-00-00');

SET SQL_MODE='NO_ZERO_DATE';

CREATE OR REPLACE TABLE y LIKE x;
ERROR 1067 (42000): Invalid default value for 'd'
```

CREATE TABLE ... SELECT

You can create a table containing data from other tables using the `CREATE ... SELECT` statement. Columns will be created in the table for each field returned by the `SELECT` query.

You can also define some columns normally and add other columns from a `SELECT`. You can also create columns in the normal way and assign them some values using the query, this is done to force a certain type or other field characteristics. The columns that are not named in the query will be placed before the others. For example:

```
CREATE TABLE test (a INT NOT NULL, b CHAR(10)) ENGINE=MyISAM
    SELECT 5 AS b, c, d FROM another_table;
```

Remember that the query just returns data. If you want to use the same indexes or the same column attributes (`[NOT] NULL`, `DEFAULT`, `AUTO_INCREMENT`, `CHECK` constraints) in the new table, you need to specify them manually. Types and sizes are not automatically preserved if no data is returned by the `SELECT` that requires the full size, and `VARCHAR` could be converted into `CHAR`. The CAST() function can be used to force the new table to use certain types.

Aliases (`AS`) are taken into account, and they should always be used when you `SELECT` an expression (function, arithmetical operation, etc.).

If an error occurs during the query, the table will not be created at all.

If the new table has a primary key or `UNIQUE` indexes, you can use the IGNORE or `REPLACE` keywords to handle duplicate key errors during the query. `IGNORE` means that the newer values must not be inserted if an identical value exists in the index. `REPLACE` means that older values must be overwritten.

If the columns in the new table are more than the rows returned by the query, the columns populated by the query will be placed after the other columns. Note that if the strict `SQL_MODE` is on, and the columns that are not named in the query do not have a `DEFAULT` value, an error will be raised and no rows will be copied.

Concurrent inserts are not used during the execution of a `CREATE ... SELECT`.

If the table already exists, an error similar to the following will be returned:

```
ERROR 1050 (42S01): Table 't' already exists
```

If the `IF NOT EXISTS` clause is used, and the table exists, a note will be produced instead of an error.

To insert rows from a query into an existing table, INSERT … SELECT can be used.

Column Definitions

```
create_definition:
  { col_name column_definition | index_definition | period_definition | CHECK (expr) }

column_definition:
  data_type
    [NOT NULL | NULL] [DEFAULT default_value | (expression)]
    [ON UPDATE [NOW | CURRENT_TIMESTAMP] [(precision)]]
    [AUTO_INCREMENT] [ZEROFILL] [UNIQUE [KEY] | [PRIMARY] KEY]
    [INVISIBLE] [{WITH|WITHOUT} SYSTEM VERSIONING]
    [COMMENT 'string'] [REF_SYSTEM_ID = value]
    [reference_definition]
  | data_type [GENERATED ALWAYS]
  AS [ ROW {START|END} [NOT NULL ENABLE] [[PRIMARY] KEY]
        | (expression) [VIRTUAL | PERSISTENT | STORED] ]
      [INVISIBLE] [UNIQUE [KEY]] [COMMENT 'string']

constraint_definition:
   CONSTRAINT [constraint_name] CHECK (expression)
```

Note:

Note:

CURRENT

MariaDB accepts the shortcut format with a `REFERENCES` clause only in `ALTER TABLE` and `CREATE TABLE` statements, but that syntax does nothing. For example:

```
CREATE TABLE b(for_key INT REFERENCES a(not_key));
```

MariaDB will attempt to apply the constraint. See Foreign Keys examples.

< 10.5

MariaDB accepts the shortcut format with a `REFERENCES` clause only in `ALTER TABLE` and `CREATE TABLE` statements, but that syntax does nothing. For example:

```
CREATE TABLE b(for_key INT REFERENCES a(not_key));
```

Each definition either creates a column in the table or specifies an index or constraint on one or more columns. See Indexes below for details on creating indexes.

Create a column by specifying a column name and a data type, optionally followed by column options. See Data Types for a full list of data types allowed in MariaDB.

NULL and NOT NULL

Use the `NULL` or `NOT NULL` options to specify that values in the column may or may not be `NULL`, respectively. By default, values may be `NULL`. See also NULL Values in MariaDB.

DEFAULT Column Option

Specify a default value using the `DEFAULT` clause. If you don't specify `DEFAULT` then the following rules apply:

- If the column is not defined with `NOT NULL`, `AUTO_INCREMENT` or `TIMESTAMP`, an explicit `DEFAULT NULL` will be added.
  Note that in MySQL, you may get an explicit `DEFAULT` for primary key parts, if not specified with NOT NULL.

The default value will be used if you INSERT a row without specifying a value for that column, or if you specify DEFAULT for that column.

CURRENT_TIMESTAMP may also be used as the default value for a DATETIME

You can use most functions in `DEFAULT`. Expressions should have parentheses around them. If you use a non deterministic function in `DEFAULT` then all inserts to the table will be replicated in row mode. You can even refer to earlier columns in the `DEFAULT` expression (excluding `AUTO_INCREMENT` columns):

```
CREATE TABLE t1 (a INT DEFAULT (1+1), b INT DEFAULT (a+1));
CREATE TABLE t2 (a BIGINT PRIMARY KEY DEFAULT UUID_SHORT());
```

The `DEFAULT` clause cannot contain any stored functions or subqueries, and a column used in the clause must already have been defined earlier in the statement.

It is possible to assign BLOB or TEXT columns a `DEFAULT` value.

You can also use DEFAULT (NEXT VALUE FOR sequence).

AUTO_INCREMENT Column Option

Use AUTO_INCREMENT to create a column whose value can be set automatically from a simple counter. You can only use `AUTO_INCREMENT` on a column with an integer type. The column must be a key, and there can only be one `AUTO_INCREMENT` column in a table. If you insert a row without specifying a value for that column (or if you specify `0`, `NULL`, or DEFAULT as the value), the actual value will be taken from the counter, with each insertion

incrementing the counter by one. You can still insert a value explicitly. If you insert a value that is greater than the current counter value, the counter is set based on the new value. An `AUTO_INCREMENT` column is implicitly `NOT NULL`. Use LAST_INSERT_ID to get the AUTO_INCREMENT value most recently used by an INSERT statement.

ZEROFILL Column Option

If the `ZEROFILL` column option is specified for a column using a numeric data type, then the column will be set to `UNSIGNED` and the spaces used by default to pad the field are replaced with zeros. `ZEROFILL` is ignored in expressions or as part of a UNION, INTERSECT, or EXCEPT. `ZEROFILL` is a non-standard MariaDB and MySQL extension.

PRIMARY KEY Column Option

Use `PRIMARY KEY` to make a column a primary key. A primary key is a special type of a unique key. There can be at most one primary key per table, and it is implicitly `NOT NULL`.

Specifying a column as a unique key creates a unique index on that column. See the Index Definitions section below for more information.

UNIQUE KEY Column Option

Use `UNIQUE KEY` (or just `UNIQUE`) to specify that all values in the column must be distinct from each other. Unless the column is `NOT NULL`, there may be multiple rows with `NULL` in the column.

```
```

When any inserts or updates occur in the table, reading the binlog shows the hidden column (@3). it causes confusion for the user; we can document these behaviours.

```
### INSERT INTO `securedb`.`t_long_keys`
### SET
###   @1=1 /* INT meta=0 nullable=0 is_null=0 */
###   @2='a' /* VARSTRING(4073) meta=4073 nullable=1 is_null=0 */
###   @3=580 /* LONGINT meta=0 nullable=1 is_null=0 */
```

```

| TABLE_ID | NAME          | POS   | MTYPE | PRTYPE | LEN  |
+----------+---------------+-------+-------+--------+------+
|       64 | a             |     0 |     6 |   1283 |    4 |
|       64 | b             |     1 |     1 | 528399 | 4073 |
|       64 | DB_ROW_HASH_1 | 65538 |     6 |   9736 |    8 |
+----------+---------------+-------+-------+--------+------+
```

See the Index Definitions section below for more information.

COMMENT Column Option

You can provide a comment for each column using the `COMMENT` clause. The maximum length is 1024 characters. Use the SHOW FULL COLUMNS statement to see column comments.

REF_SYSTEM_ID

`REF_SYSTEM_ID` can be used to specify Spatial Reference System IDs for spatial data type columns. For example:

```
CREATE TABLE t1(g GEOMETRY(9,4) REF_SYSTEM_ID=101);
```

Generated Columns

A generated column is a column in a table that cannot explicitly be set to a specific value in a DML query. Instead, its value is automatically generated based on an expression. This expression might generate the value based on the values of other columns in the table, or it might generate the value by calling built-in functions or user-defined functions (UDFs).

There are two types of generated columns:

- `PERSISTENT` or `STORED`: This type's value is actually stored in the table.
- `VIRTUAL`: This type's value is not stored at all. Instead, the value is generated dynamically when the table is queried. This type is the default.

Generated columns are also sometimes called computed columns or virtual columns.

For a complete description about generated columns and their limitations, see Generated (Virtual and Persistent/Stored) Columns.

COMPRESSED

Certain columns may be compressed. See Storage-Engine Independent Column Compression.

INVISIBLE

Columns may be made invisible, and hidden in certain contexts. See Invisible Columns.

WITH SYSTEM VERSIONING Column Option

Columns may be explicitly marked as included from system versioning. See System-versioned tables for details.

WITHOUT SYSTEM VERSIONING Column Option

Columns may be explicitly marked as excluded from system versioning. See System-versioned tables for details.

Index Definitions

```
index_definition:
    {INDEX|KEY} [index_name] [index_type] (index_col_name,...) [index_option] ...
  {{{|}}} {FULLTEXT|SPATIAL} [INDEX|KEY] [index_name] (index_col_name,...) [index_option] ...
  {{{|}}} [CONSTRAINT [symbol]] PRIMARY KEY [index_type] (index_col_name,...) [index_option] ...
  {{{|}}} [CONSTRAINT [symbol]] UNIQUE [INDEX|KEY] [index_name] [index_type] (index_col_name,...)
[index_option] ...
  {{{|}}} [CONSTRAINT [symbol]] FOREIGN KEY [index_name] (index_col_name,...) reference_definition

index_col_name:

reference_option:
    RESTRICT | CASCADE | SET NULL | NO ACTION
```

`INDEX` and `KEY` are synonyms.

Index names are optional, if not specified an automatic name will be assigned. Index name are needed to drop indexes and appear in error messages when a constraint is violated.

For limits on InnoDB indexes, see InnoDB Limitations.

Index Categories

Plain Indexes

Plain indexes are regular indexes that are not unique, and are not acting as a primary key or a foreign key. They are also not the “specialized” `FULLTEXT` or `SPATIAL` indexes.

See Getting Started with Indexes: Plain Indexes for more information.

PRIMARY KEY

For `PRIMARY KEY` indexes, you can specify a name for the index, but it is ignored, and the name of the index is always `PRIMARY`. A warning is explicitly issued if a name is specified. Before then, the name was silently ignored.

See Getting Started with Indexes: Primary Key for more information.

UNIQUE

The `UNIQUE` keyword means that the index will not accept duplicated values, except for NULLs. An error will raise if you try to insert duplicate values in a UNIQUE index.

For `UNIQUE` indexes, you can specify a name for the constraint, using the `CONSTRAINT` keyword. That name will be used in error messages.

> **CURRENT**
>
> > **Note:**
> >
> > Unique, if index type is not specified, is normally a BTREE index that can also be used by the optimizer to find rows. If the key is longer than the max key length for the used storage engine, a HASH key will be created. This enables MariaDB to enforce uniqueness for any type or number of columns.
>
> **< 10.5**
>
> -

See Getting Started with Indexes: Unique Index for more information.

FOREIGN KEY

For `FOREIGN KEY` indexes, a reference definition must be provided.

For `FOREIGN KEY` indexes, you can specify a name for the constraint, using the `CONSTRAINT` keyword. That name will be used in error messages.

First, you have to specify the name of the target (parent) table and a column or a column list which must be indexed and whose values must match to the foreign key’s values. The `MATCH` clause is accepted to improve the compatibility with other DBMS’s, but has no meaning in MariaDB. The `ON DELETE` and `ON UPDATE` clauses specify what must be done when a `DELETE` (or a `REPLACE`) statements attempts to delete a referenced row from the parent table, and when an `UPDATE` statement attempts to modify the referenced foreign key columns in a parent table row, respectively. The following options are allowed:

- `RESTRICT`: The delete/update operation is not performed. The statement terminates with a 1451 error (SQLSTATE ‘2300’).
- `NO ACTION`: Synonym for `RESTRICT`.
- `CASCADE`: The delete/update operation is performed in both tables.
- `SET NULL`: The update or delete goes ahead in the parent table, and the corresponding foreign key fields in the child table are set to `NULL`. (They must not be defined as `NOT NULL` for this to succeed).

- `SET DEFAULT`: This option is currently implemented only for the PBXT storage engine, which is disabled by default and no longer maintained. It sets the child table's foreign key fields to their `DEFAULT` values when the referenced parent table key entries are updated or deleted.

If either clause is omitted, the default behavior for the omitted clause is `RESTRICT`.

See Foreign Keys for more information.

FULLTEXT

Use the `FULLTEXT` keyword to create full-text indexes.

See Full-Text Indexes for more information.

SPATIAL

Use the `SPATIAL` keyword to create geometric indexes.

See SPATIAL INDEX for more information.

Index Options

KEY_BLOCK_SIZE Index Option

The `KEY_BLOCK_SIZE` index option is similar to the KEY_BLOCK_SIZE table option.

With the InnoDB storage engine, if you specify a non-zero value for the `KEY_BLOCK_SIZE` table option for the whole table, then the table will implicitly be created with the ROW_FORMAT table option set to `COMPRESSED`. However, this does not happen if you just set the `KEY_BLOCK_SIZE` index option for one or more indexes in the table. The InnoDB storage engine ignores the `KEY_BLOCK_SIZE` index option. However, the SHOW CREATE TABLE statement may still report it for the index.

For information about the `KEY_BLOCK_SIZE` index option, see the KEY_BLOCK_SIZE table option below.

ADAPTIVE_HASH_INDEX Index Option

> **Note:**
>
> Added in **MariaDB 13.1.1** (MDEV-37070).

The `ADAPTIVE_HASH_INDEX` index option takes the same `DEFAULT`, `YES`, and `NO` values as the ADAPTIVE_HASH_INDEX table option, but applies to a single index. When set to `YES` or `NO`, it overrides the table-level setting for that index. This option applies only to InnoDB.

Advanced Adaptive Hash Index Tuning Options

> **Note:**
>
> Added in **MariaDB 13.1.1** (MDEV-37070).

Three additional InnoDB index options give fine-grained control over how the adaptive hash index is built for an index:

Option	Values	Effect
`COMPLETE_FIELDS`	`0` to the number of columns the index is defined on (maximum `64`)	Number of complete index columns to include in the hash.

Option	Values	Effect
`BYTES_FROM_INCOMPLETE_FIELD`	`0` to `16383`	Number of leading bytes to take from the next column, beyond those covered by `COMPLETE_FIELDS`. Only meaningful for `memcmp()`-comparable index fields such as `VARBINARY` or integer types. For example, a 3-byte prefix on an `INT` returns one hash value for 0..255, another for 256..511, and so on.
`FOR_EQUAL_HASH_POINT_TO_LAST_RECORD`	`DEFAULT`, `YES`, `NO`	For a set of records that share the same hash value, controls which record the hash entry points to: `NO` points to the first record, `YES` points to the last.

The default for all three is unset (automatic), in which case InnoDB chooses the values from its internal heuristic.

> **Warning:**
>
> These are power-user options and are not needed for typical workloads. They override InnoDB's internal heuristic, which is computed and *then* replaced by the values you supply. Because the three options work together, set **all three** to known-good values whenever you set even one of them — setting only one or two leaves the others to interact with the overridden heuristic and can produce unintended results.
>
> InnoDB does not expose the values its heuristic would otherwise compute, so suitable settings must be derived from prior knowledge of the data and confirmed through performance testing.

The main reason to fix these values is to avoid *adaptive-hash-index churn*: when an index's lookup pattern is not constant, the internal heuristic keeps changing its parameters, repeatedly destroying and rebuilding the hash index. Pinning the parameters keeps a single hash index in place — less optimal for some queries, but stable and beneficial for the rest, instead of being continually rebuilt.

These options apply only to InnoDB, and only on servers built with adaptive hash index support.

Index Types

Each storage engine supports some or all index types. See Storage Engine Index Types for details on permitted index types for each storage engine.

Different index types are optimized for different kind of operations:

- `BTREE` is the default type, and normally is the best choice. It is supported by all storage engines. It can be used to compare a column's value with a value using the =, >, >=, <, <=, `BETWEEN`, and `LIKE` operators. `BTREE` can also be used to find `NULL` values. Searches against an index prefix are possible.
- `HASH` is only supported by the MEMORY storage engine. `HASH` indexes can only be used for =, <=, and >= comparisons. It can not be used for the `ORDER BY` clause. Searches against an index prefix are not possible.
- `RTREE` is the default for SPATIAL indexes, but if the storage engine does not support it `BTREE` can be used.

> **CURRENT**
>
> Index columns names are listed between parenthesis. After each column, a prefix length can be specified. If no length is specified, the whole column will be indexed. `ASC` and `DESC` can be specified. Individual columns in the index can be explicitly sorted in ascending or descending order. This can be useful for optimizing certain ORDER BY cases (MDEV-13756, MDEV-26938, MDEV-26939, MDEV-26996). Not only ascending, but also descending, indexes can be used to optimize MIN() and MAX() (MDEV-27576).
>
> **< 11.4 / 10.8**
>
> Index columns names are listed between parenthesis. After each column, a prefix length can be specified. If no length is specified, the whole column will be indexed. `ASC` and `DESC` can be specified. Prior to MariaDB 10.8, this was only for compatibility with other DBMSs, but had no meaning in MariaDB. From MariaDB 10.8, individual columns in the index can now be explicitly sorted in ascending or descending order. This can be useful for

> optimizing certain ORDER BY cases (MDEV-13756, MDEV-26938, MDEV-26939, MDEV-26996). From MariaDB 11.4.0, not only ascending, but also descending, indexes can now be used to optimize MIN() and MAX() (MDEV-27576).

The maximum number of parts in an index is 32.

WITH PARSER Index Option

The `WITH PARSER` index option only applies to FULLTEXT indexes and contains the fulltext parser name. The fulltext parser must be an installed plugin.

VISIBLE Index Option

> **CURRENT**
>
> Indexes can be declared visible. This is the default and it shows up in SHOW CREATE TABLE.
>
> **< 10.5.3**
>
> Indexes cannot be declared visible.

COMMENT Index Option

A comment of up to 1024 characters is permitted with the `COMMENT` index option.

The `COMMENT` index option allows you to specify a comment with user-readable text describing what the index is for. This information is not used by the server itself.

IGNORED / NOT IGNORED

> **CURRENT**
>
> Indexes can be specified to be ignored by the optimizer. See Ignored Indexes.
>
> **< 10.6.0**
>
> Indexes can be specified to be ignored by the optimizer. See Ignored Indexes.

Periods

```
period_definition:
    PERIOD FOR [time_period_name | SYSTEM_TIME] (start_column_name, end_column_name)
```

MariaDB supports System-versioned tables, Application-time-period tables or Bitemporal Tables.

Constraint Expressions

MariaDB introduced two ways to define a constraint:

- `CHECK(expression)` given as part of a column definition.
- `CONSTRAINT [constraint_name] CHECK (expression)`

Before a row is inserted or updated, all constraints are evaluated in the order they are defined. If any constraints fails, then the row will not be updated.
One can use most deterministic functions in a constraint, including UDFs.

```
CREATE TABLE t1 (a INT CHECK(a>0) ,b INT CHECK (b> 0), CONSTRAINT abc CHECK (a>b));
```

If you use the second format and you don't give a name to the constraint, then the constraint will get a auto generated name. This is done so that you can later delete the constraint with ALTER TABLE DROP constraint_name.

One can disable all constraint expression checks by setting the variable `check_constraint_checks` to `OFF`. This is useful for example when loading a table that violates some constraints that you want to later find and fix in SQL.

See CONSTRAINT for more information.

Table Options

For each individual table you create (or alter), you can set some table options. The general syntax for setting options is:

```
<OPTION_NAME> = <option_value>, [<OPTION_NAME> = <option_value> ...]
```

The equal sign is optional.

Some options are supported by the server and can be used for all tables, no matter what storage engine they use; other options can be specified for all storage engines, but have a meaning only for some engines. Also, engines can extend CREATE TABLE with new options.

If the `IGNORE_BAD_TABLE_OPTIONS` SQL_MODE is enabled, wrong table options generate a warning; otherwise, they generate an error.

```
table_option:
    [STORAGE] ENGINE [=] engine_name
  | ADAPTIVE_HASH_INDEX [=] {DEFAULT | YES | NO}
  | AUTO_INCREMENT [=] number
  | AVG_ROW_LENGTH [=] number
  | [DEFAULT] CHARACTER SET [=] <a data-footnote-ref href="#user-content-fn-7">charset_name</a>
  | CHECKSUM [=] {0 | 1}
  | [DEFAULT] COLLATE [=] <a data-footnote-ref href="#user-content-fn-7">collation_name</a>
  | COMMENT [=] 'string'
  | CONNECTION [=] 'connect_string'
  | DATA DIRECTORY [=] 'absolute path to directory'
  | DELAY_KEY_WRITE [=] {0 | 1}
  | ENCRYPTED [=] {YES | NO}
  | ENCRYPTION_KEY_ID [=] number
  | IETF_QUOTES [=] {YES | NO}
  | INDEX DIRECTORY [=] 'absolute path to directory'
  | INSERT_METHOD [=] { NO | FIRST | LAST }
  | KEY_BLOCK_SIZE [=] number
  | MAX_ROWS [=] number
  | MIN_ROWS [=] number
  | PACK_KEYS [=] {0 | 1 | DEFAULT}
  | PAGE_CHECKSUM [=] {0 | 1}
  | PAGE_COMPRESSED [=] {0 | 1}
  | PAGE_COMPRESSION_LEVEL [=] {0 .. 9}
  | PASSWORD [=] 'string'
  | ROW_FORMAT [=] {DEFAULT|DYNAMIC|FIXED|COMPRESSED|REDUNDANT|COMPACT|PAGE}
  | SEQUENCE [=] {0|1}
  | STATS_AUTO_RECALC [=] {DEFAULT|0|1}
  | STATS_PERSISTENT [=] {DEFAULT|0|1}
  | STATS_SAMPLE_PAGES [=] {DEFAULT|number}
  | TABLESPACE tablespace_name
  | TRANSACTIONAL [=]  {0 | 1}
  | UNION [=] (tbl_name[,tbl_name]...)
  | WITH SYSTEM VERSIONING
```

[STORAGE] ENGINE

`[STORAGE] ENGINE` specifies a storage engine for the table. If this option is not used, the default storage engine is used instead. That is, the default_storage_engine session option value if it is set, or the value specified for the `--default-storage-engine` mariadbd startup option, or the default storage engine, InnoDB. If the specified storage engine is not installed and active, the default value will be used, unless the `NO_ENGINE_SUBSTITUTION` SQL MODE is set (default). This is only true for `CREATE TABLE`, not for `ALTER TABLE`. For a list of storage engines that are present in your server, issue a SHOW ENGINES.

ADAPTIVE_HASH_INDEX

> **Note:**
>
> The `ADAPTIVE_HASH_INDEX` table and index options were added in **MariaDB 13.1.1** (MDEV-37070).

`ADAPTIVE_HASH_INDEX` controls whether the InnoDB adaptive hash index (AHI) is used for an individual InnoDB table. It takes one of three values:

- `DEFAULT` — no per-table preference: the table follows the global innodb_adaptive_hash_index setting. This is the default, and removes the option from the stored table definition.
- `YES` — request the adaptive hash index for this table. AHI is built for the table only when it is also enabled at the server level (`innodb_adaptive_hash_index` set to `ON` or `IF_SPECIFIED`).
- `NO` — never use the adaptive hash index for this table, even when it is enabled at the server level.

The option only affects InnoDB tables, and only on servers built with adaptive hash index support. The same option can be set per index (see ADAPTIVE_HASH_INDEX Index Option); an index-level `YES` or `NO` overrides the table-level setting for that index.

AUTO_INCREMENT

`AUTO_INCREMENT` specifies the initial value for the AUTO_INCREMENT primary key. This works for MyISAM, Aria, InnoDB, MEMORY, and ARCHIVE tables. You can change this option with `ALTER TABLE`, but in that case the new value must be higher than the highest value which is present in the `AUTO_INCREMENT` column. If the storage engine does not support this option, you can insert (and then delete) a row having the wanted value - 1 in the `AUTO_INCREMENT` column.

AVG_ROW_LENGTH

`AVG_ROW_LENGTH` is the average rows size. It only applies to tables using MyISAM and Aria storage engines that have the ROW_FORMAT table option set to `FIXED` format.

MyISAM uses `MAX_ROWS` and `AVG_ROW_LENGTH` to decide the maximum size of a table (default: 256TB, or the maximum file size allowed by the system).

[DEFAULT] CHARACTER SET/CHARSET

`[DEFAULT] CHARACTER SET` (or `[DEFAULT] CHARSET`) is used to set a default character set for the table. This is the character set used for all columns where an explicit character set is not specified. If this option is omitted or `DEFAULT` is specified, the database's default character set will be used (except for the JSON data type, which is utf8mb4 by default). See Setting Character Sets and Collations for details on setting the character sets.

CHECKSUM/TABLE_CHECKSUM

`CHECKSUM` (or `TABLE_CHECKSUM`) can be set to 1 to maintain a live checksum for all table's rows. This makes write operations slower, but CHECKSUM TABLE will be very fast. This option is only supported for MyISAM and Aria tables.

[DEFAULT] COLLATE

`[DEFAULT] COLLATE` is used to set a default collation for the table. This is the collation used for all columns where an explicit character set is not specified. If this option is omitted or `DEFAULT` is specified, the database's default option will be used (except for the JSON data type, which uses utf8mb4_bin by default). See Setting Character Sets and Collations for details on setting the collations

COMMENT

`COMMENT` is a comment for the table. The maximum length is 2048 characters. Also used to define table parameters when creating a Spider table.

CONNECTION

`CONNECTION` is used to specify a server name or a connection string for a Spider, CONNECT, Federated or FederatedX table.

DATA DIRECTORY/INDEX DIRECTORY

`DATA DIRECTORY` and `INDEX DIRECTORY` are supported for MyISAM and Aria, and DATA DIRECTORY is also supported by InnoDB if the innodb_file_per_table server system variable is enabled, but only in CREATE TABLE, not in ALTER TABLE. So, carefully choose a path for InnoDB tables at creation time, because it cannot be changed without dropping and re-creating the table. These options specify the paths for data files and index files, respectively. If these options are omitted, the database's directory will be used to store data files and index files. Note that these table options do not work for partitioned tables (use the partition options instead), or if the server has been invoked with the –skip-symbolic-links startup option. To avoid the overwriting of old files with the same name that could be present in the directories, you can use the –keep_files_on_create option (an error will be issued if files already exist). These options are ignored if the `NO_DIR_IN_CREATE` SQL_MODE is enabled (useful for replicas). Also note that symbolic links cannot be used for InnoDB tables.

`DATA DIRECTORY` works by creating symlinks from where the table would normally have been (inside the datadir) to where the option specifies. For security reasons, to avoid bypassing the privilege system, the server does not permit symlinks inside the datadir. Therefore, `DATA DIRECTORY` cannot be used to specify a location inside the datadir. An attempt to do so will result in an error `1210 (HY000) Incorrect arguments to DATA DIRECTORY`.

DELAY_KEY_WRITE

`DELAY_KEY_WRITE` is supported by MyISAM and Aria, and can be set to 1 to speed up write operations. In that case, when data are modified, the indexes are not updated until the table is closed. Writing the changes to the index file altogether can be much faster. However, note that this option is applied only if the `delay_key_write` server variable is set to 'ON'. If it is 'OFF' the delayed index writes are always disabled, and if it is 'ALL' the delayed index writes are always used, disregarding the value of `DELAY_KEY_WRITE`.

ENCRYPTED

The `ENCRYPTED` table option can be used to manually set the encryption status of an InnoDB table. See InnoDB Encryption for more information.

Aria does not support the `ENCRYPTED` table option. See MDEV-18049.

See Data-at-Rest Encryption for more information.

ENCRYPTION_KEY_ID

The `ENCRYPTION_KEY_ID` table option can be used to manually set the encryption key of an InnoDB table. See InnoDB Encryption for more information.

Aria does not support the `ENCRYPTION_KEY_ID` table option. See MDEV-18049.

See Data-at-Rest Encryption for more information.

IETF_QUOTES

For the CSV storage engine, the `IETF_QUOTES` option, when set to `YES`, enables IETF-compatible parsing of embedded quote and comma characters. Enabling this option for a table improves compatibility with other tools that use CSV, but is not compatible with MySQL CSV tables, or MariaDB CSV tables created without this option. Disabled by default.

INSERT_METHOD

`INSERT_METHOD` is only used with MERGE tables. This option determines in which underlying table the new rows should be inserted. If you set it to 'NO' (which is the default) no new rows can be added to the table (but you will still be able to perform `INSERT`s directly against the underlying tables). `FIRST` means that the rows are inserted into the first table, and `LAST` means that they are inserted into the last table.

KEY_BLOCK_SIZE

`KEY_BLOCK_SIZE` is used to determine the size of key blocks, in bytes or kilobytes. However, this value is just a hint, and the storage engine could modify or ignore it. If `KEY_BLOCK_SIZE` is set to 0, the storage engine's default value will be used.

With the InnoDB storage engine, if you specify a non-zero value for the `KEY_BLOCK_SIZE` table option for the whole table, then the table will implicitly be created with the ROW_FORMAT table option set to `COMPRESSED`.

MIN_ROWS/MAX_ROWS

`MIN_ROWS` and `MAX_ROWS` let the storage engine know how many rows you are planning to store as a minimum and as a maximum. These values will not be used as real limits, but they help the storage engine to optimize the table. `MIN_ROWS` is only used by MEMORY storage engine to decide the minimum memory that is always allocated. `MAX_ROWS` is used to decide the minimum size for indexes.

PACK_KEYS

`PACK_KEYS` can be used to determine whether the indexes will be compressed. Set it to 1 to compress all keys. With a value of 0, compression will not be used. With the `DEFAULT` value, only long strings will be compressed. Uncompressed keys are faster.

PAGE_CHECKSUM

`PAGE_CHECKSUM` is only applicable to Aria tables, and determines whether indexes and data should use page checksums for extra safety.

PAGE_COMPRESSED

`PAGE_COMPRESSED` is used to enable InnoDB page compression for InnoDB tables.

PAGE_COMPRESSION_LEVEL

`PAGE_COMPRESSION_LEVEL` is used to set the compression level for InnoDB page compression for InnoDB tables. The table must also have the PAGE_COMPRESSED table option set to `1`.

Valid values for `PAGE_COMPRESSION_LEVEL` are 1 (the best speed) through 9 (the best compression), .

PASSWORD

`PASSWORD` is unused.

RAID_TYPE

`RAID_TYPE` is an obsolete option, as the raid support has been disabled since MySQL 5.0.

ROW_FORMAT

The `ROW_FORMAT` table option specifies the row format for the data file. Possible values are engine-dependent.

Supported MyISAM Row Formats

For MyISAM, the supported row formats are:

- `FIXED`
- `DYNAMIC`
- `COMPRESSED`

The `COMPRESSED` row format can only be set by the myisampack command line tool.

See MyISAM Storage Formats for more information.

Supported Aria Row Formats

For Aria, the supported row formats are:

- `PAGE`
- `FIXED`
- `DYNAMIC`.

See Aria Storage Formats for more information.

Supported InnoDB Row Formats

For InnoDB, the supported row formats are:

- `COMPACT`
- `REDUNDANT`
- `COMPRESSED`
- `DYNAMIC`.

If the `ROW_FORMAT` table option is set to `FIXED` for an InnoDB table, then the server will either return an error or a warning depending on the value of the innodb_strict_mode system variable. If the innodb_strict_mode system variable is set to `OFF`, then a warning is issued, and MariaDB will create the table using the default row format for the specific MariaDB server version. If the innodb_strict_mode system variable is set to `ON`, then an error will be raised.

See InnoDB Storage Formats for more information.

Other Storage Engines and ROW_FORMAT

Other storage engines do not support the `ROW_FORMAT` table option.

SEQUENCE

If the table is a sequence, then it will have the `SEQUENCE` set to `1`.

STATS_AUTO_RECALC

`STATS_AUTO_RECALC` indicates whether to automatically recalculate persistent statistics (see `STATS_PERSISTENT`, below) for an InnoDB table.
If set to `1`, statistics will be recalculated when more than 10% of the data has changed. When set to `0`, stats will be

recalculated only when an ANALYZE TABLE is run. If set to `DEFAULT`, or left out, the value set by the innodb_stats_auto_recalc system variable applies. See InnoDB Persistent Statistics.

STATS_PERSISTENT

`STATS_PERSISTENT` indicates whether the InnoDB statistics created by ANALYZE TABLE will remain on disk or not. It can be set to `1` (on disk), `0` (not on disk, the pre-MariaDB 10 behavior), or `DEFAULT` (the same as leaving out the option), in which case the value set by the innodb_stats_persistent system variable will apply. Persistent statistics stored on disk allow the statistics to survive server restarts, and provide better query plan stability. See InnoDB Persistent Statistics.

STATS_SAMPLE_PAGES

`STATS_SAMPLE_PAGES` indicates how many pages are used to sample index statistics. If 0 or DEFAULT, the default value, the innodb_stats_sample_pages value is used. See InnoDB Persistent Statistics.

TRANSACTIONAL

`TRANSACTIONAL` is only applicable for Aria tables. In future Aria tables created with this option will be fully transactional, but currently this provides a form of crash protection. See Aria Storage Engine for more details.

UNION

`UNION` must be specified when you create a MERGE table. This option contains a comma-separated list of MyISAM tables which are accessed by the new table. The list is enclosed between parenthesis. Example: `UNION = (t1,t2)`

WITH SYSTEM VERSIONING

`WITH SYSTEM VERSIONING` is used for creating System-versioned tables.

Partitions

```
partition_options:
    PARTITION BY
        { [LINEAR] HASH(expr)
        | [LINEAR] KEY(column_list)
        | RANGE(expr)
        | LIST(expr)
        | SYSTEM_TIME [INTERVAL time_quantity <a data-footnote-ref href="#user-content-fn-
8">time_unit</a>] [LIMIT num] }
    [PARTITIONS num]
    [SUBPARTITION BY
        { [LINEAR] HASH(expr)
        | [LINEAR] KEY(column_list) }
      [SUBPARTITIONS num]
    ]
    [(partition_definition [, partition_definition] ...)]

partition_definition:
    [PARTITION] partition_name
        [VALUES {LESS THAN {(expr) | MAXVALUE} | IN (value_list)}]
        [[STORAGE] ENGINE [=] engine_name]
        [COMMENT [=] 'comment_text' ]
        [DATA DIRECTORY [=] 'data_dir']
        [INDEX DIRECTORY [=] 'index_dir']
        [MAX_ROWS [=] max_number_of_rows]
        [MIN_ROWS [=] min_number_of_rows]
        [TABLESPACE [=] tablespace_name]
        [NODEGROUP [=] node_group_id]
        [(subpartition_definition [, subpartition_definition] ...)]

subpartition_definition:
    SUBPARTITION logical_name
        [[STORAGE] ENGINE [=] engine_name]
        [COMMENT [=] 'comment_text' ]
        [DATA DIRECTORY [=] 'data_dir']
        [INDEX DIRECTORY [=] 'index_dir']
        [MAX_ROWS [=] max_number_of_rows]
        [MIN_ROWS [=] min_number_of_rows]
        [TABLESPACE [=] tablespace_name]
        [NODEGROUP [=] node_group_id]
```

If the `PARTITION BY` clause is used, the table will be partitioned. A partition method must be explicitly indicated for partitions and subpartitions. Partition methods are:

- `[LINEAR] HASH` creates a hash key which will be used to read and write rows. The partition function can be any valid SQL expression which returns an `INTEGER` number. Thus, it is possible to use the `HASH` method on an integer column, or on functions which accept integer columns as an argument. However, `VALUES LESS THAN` and `VALUES IN` clauses can not be used with `HASH`. An example:

```
CREATE TABLE t1 (a INT, b CHAR(5), c DATETIME)
    PARTITION BY HASH ( YEAR(c) );
```

`[LINEAR] HASH` can be used for subpartitions, too.

- `[LINEAR] KEY` is similar to `HASH`, but the index has an even distribution of data. Also, the expression can only be a column or a list of columns. `VALUES LESS THAN` and `VALUES IN` clauses can not be used with `KEY`.
- RANGE partitions the rows using on a range of values, using the `VALUES LESS THAN` operator. `VALUES IN` is not allowed with `RANGE`. The partition function can be any valid SQL expression which returns a single value.
- LIST assigns partitions based on a table's column with a restricted set of possible values. It is similar to `RANGE`, but `VALUES IN` must be used for at least 1 columns, and `VALUES LESS THAN` is disallowed.

- `SYSTEM_TIME` partitioning is used for System-versioned tables to store historical data separately from current data.

Only HASH and KEY can be used for subpartitions, and they can be `[LINEAR]`.

It is possible to define up to 8092 partitions and subpartitions.

The number of defined partitions can be optionally specified as `PARTITION count`. This can be done to avoid specifying all partitions individually. But you can also declare each individual partition and, additionally, specify a `PARTITIONS count` clause; in the case, the number of `PARTITION`s must equal count.

Also see Partitioning Types Overview.

> **CURRENT**
>
> The `PARTITION` keyword is optional as part of the partition definition. Instead of this:
>
> ```
> CREATE OR REPLACE TABLE t1 (x INT)
>   PARTITION BY RANGE(x) (
>     PARTITION p1 VALUES LESS THAN (10),
>     PARTITION p2 VALUES LESS THAN (20),
>     PARTITION p3 VALUES LESS THAN (30),
>     PARTITION p4 VALUES LESS THAN (40),
>     PARTITION p5 VALUES LESS THAN (50),
>     PARTITION pn VALUES LESS THAN MAXVALUE);
> ```
>
> The following can be used:
>
> ```
> CREATE OR REPLACE TABLE t1 (x INT)
>   PARTITION BY RANGE(x) (
>     p1 VALUES LESS THAN (10),
>     p2 VALUES LESS THAN (20),
>     p3 VALUES LESS THAN (30),
>     p4 VALUES LESS THAN (40),
>     p5 VALUES LESS THAN (50),
>     pn VALUES LESS THAN MAXVALUE);
> ```
>
> **< 10.7.1**
>
> The `PARTITION` keyword is not optional as part of the partition definition. You must use this syntax:
>
> ```
> CREATE OR REPLACE TABLE t1 (x INT)
>   PARTITION BY RANGE(x) (
>     PARTITION p1 VALUES LESS THAN (10),
>     PARTITION p2 VALUES LESS THAN (20),
>     PARTITION p3 VALUES LESS THAN (30),
>     PARTITION p4 VALUES LESS THAN (40),
>     PARTITION p5 VALUES LESS THAN (50),
>     PARTITION pn VALUES LESS THAN MAXVALUE);
> ```

Sequences

`CREATE TABLE` can also be used to create a SEQUENCE. See CREATE SEQUENCE and Sequence Overview.

Atomic DDL

> **CURRENT**
>
> MariaDB supports Atomic DDL. `CREATE TABLE` is atomic, except for `CREATE OR REPLACE`, which are only crash-safe.
>
> **< 10.6.1**

-

Examples

```
CREATE TABLE IF NOT EXISTS test (
a BIGINT AUTO_INCREMENT PRIMARY KEY,
name VARCHAR(128) CHARSET utf8,
KEY name (name(32))
) ENGINE=InnoDB DEFAULT CHARSET latin1;
```

This example shows a couple of things:

- Usage of `IF NOT EXISTS`; If the table already existed, it will not be created. There will not be any error for the client, just a warning.
- How to create a `PRIMARY KEY` that is automatically generated.
- How to specify a table-specific character set and another for a column.
- How to create an index (`name`) that is only partly indexed (to save space).

The following clauses will work:

```
CREATE TABLE t1(
  a INT DEFAULT (1+1),
  b INT DEFAULT (a+1),
  expires DATETIME DEFAULT(NOW() + INTERVAL 1 YEAR),
  x BLOB DEFAULT USER()
);
```

DROP TABLE

Syntax

```
DROP [TEMPORARY] TABLE [IF EXISTS] [/*COMMENT TO SAVE*/]
    tbl_name [, tbl_name] ...
    [WAIT n|NOWAIT]
    [RESTRICT | CASCADE]
```

Description

`DROP TABLE` removes one or more tables. You must have the `DROP` privilege for each table. All table data and the table definition are removed, as well as triggers associated to the table, so be careful with this statement! If any of

the tables named in the argument list do not exist, MariaDB returns an error indicating by name which non-existing tables it was unable to drop, but it also drops all of the tables in the list that do exist.

Important: When a table is dropped, user privileges on the table are not automatically dropped. See GRANT.

If another thread is using the table in an explicit transaction or an autocommit transaction, then the thread acquires a metadata lock (MDL) on the table. The `DROP TABLE` statement will wait in the "Waiting for table metadata lock" thread state until the MDL is released. MDLs are released in the following cases:

- If an MDL is acquired in an explicit transaction, then the MDL will be released when the transaction ends.
- If an MDL is acquired in an autocommit transaction, then the MDL will be released when the statement ends.
- Transactional and non-transactional tables are handled the same.

Note that for a partitioned table, `DROP TABLE` permanently removes the table definition, all of its partitions, and all of the data which was stored in those partitions. It also removes the partitioning definition (.par) file associated with the dropped table.

For each referenced table, `DROP TABLE` drops a temporary table with that name, if it exists. If it does not exist, and the `TEMPORARY` keyword is not used, it drops a non-temporary table with the same name, if it exists. The `TEMPORARY` keyword ensures that a non-temporary table will not accidentally be dropped.

Use `IF EXISTS` to prevent an error from occurring for tables that do not exist. A `NOTE` is generated for each non-existent table when using `IF EXISTS`. See SHOW WARNINGS.

If a foreign key references this table, the table cannot be dropped. In this case, it is necessary to drop the foreign key first.

`RESTRICT` and `CASCADE` are allowed to make porting from other database systems easier. In MariaDB, they do nothing.

The comment before the table names (`/*COMMENT TO SAVE*/`) is stored in the binary log. That feature can be used by replication tools to send their internal messages.

It is possible to specify table names as `db_name.tab_name`. This is useful to delete tables from multiple databases with one statement. See Identifier Qualifiers for details.

The DROP privilege is required to use `DROP TABLE` on non-temporary tables. For temporary tables, no privilege is required, because such tables are only visible for the current session.

Note: `DROP TABLE` automatically commits the current active transaction, unless you use the `TEMPORARY` keyword.

> **CURRENT**
>
> `DROP TABLE` reliably deletes table remnants inside a storage engine even if the `.frm` file is missing.
>
> **< 10.5.4**
>
> `DROP TABLE` does **not** reliably delete table remnants inside a storage engine even if the `.frm` file is missing. A missing `.frm` file will result in the statement failing.

WAIT/NOWAIT

Set the lock wait timeout. See WAIT and NOWAIT.

DROP TABLE in replication

`DROP TABLE` has the following characteristics in replication:

- `DROP TABLE IF EXISTS` are always logged.

- `DROP TABLE` without `IF EXISTS` for tables that don't exist are not written to the binary log.
- Dropping of `TEMPORARY` tables are prefixed in the log with `TEMPORARY`. These drops are only logged when running statement or mixed mode replication.
- One `DROP TABLE` statement can be logged with up to 3 different `DROP` statements:
  - `DROP TEMPORARY TABLE list_of_non_transactional_temporary_tables`
  - `DROP TEMPORARY TABLE list_of_transactional_temporary_tables`
  - `DROP TABLE list_of_normal_tables`

`DROP TABLE` on the primary is treated on the replica as `DROP TABLE IF EXISTS`. You can change that by setting slave-ddl-exec-mode to `STRICT`.

Dropping an Internal #sql-… Table

> **CURRENT**
>
> DROP TABLE is atomic.
>
> **< 10.6**
>
> if the mariadbd process is killed during an ALTER TABLE, you may find a table named #sql-… in your data directory. These temporary tables will always be deleted automatically.
>
> If you want to delete one of these tables explicitly you can do so by using the following syntax:
>
> ```
> DROP TABLE `#mysql50##sql-...`;
> ```
>
> When running an `ALTER TABLE…ALGORITHM=INPLACE` that rebuilds the table, InnoDB will create an internal `#sql-ib` table.
>
> The same name as the .frm file is used for the intermediate copy of the table. The #sql-ib names are used by TRUNCATE and delayed DROP.
>
> The #sql-ib tables will be deleted automatically.

Dropping All Tables in a Database

The best way to drop all tables in a database is by executing DROP DATABASE, which will drop the database itself, and all tables in it.

However, if you want to drop all tables in the database, but you also want to keep the database itself and any other non-table objects in it, then you would need to execute `DROP TABLE` to drop each individual table. You can construct these `DROP TABLE` commands by querying the TABLES table in the information_schema database. For example:

```
SELECT CONCAT('DROP TABLE IF EXISTS `', TABLE_SCHEMA, '`.`', TABLE_NAME, '`;')
FROM information_schema.TABLES
WHERE TABLE_SCHEMA = 'mydb';
```

Atomic DROP TABLE

MariaDB starting with 10.6.1

> **CURRENT**
>
> `DROP TABLE` for a single table is atomic (MDEV-25180) for most engines, including InnoDB, MyRocks, MyISAM and Aria. This means that if there is a crash (server down or power outage) during `DROP TABLE`, all tables that have been processed so far will be completely dropped, including related trigger files and status entries, and the binary log will include a `DROP TABLE` statement for the dropped tables. Tables for which the drop had not started

will be left intact. `DROP TABLE` was extended to be able to delete a table that was only partly dropped (MDEV-11412), as explained above. Atomic `DROP TABLE` is the final piece to make `DROP TABLE` fully reliable. Dropping multiple tables is crash-safe. See Atomic DDL for more information.

< 10.6.1

There is a small chance that, during a server crash happening in the middle of `DROP TABLE`, some storage engines that were using multiple storage files, like MyISAM, could have only a part of its internal files dropped. In MariaDB 10.5, `DROP TABLE` was extended to be able to delete a table that was only partly dropped (MDEV-11412) as explained above. Atomic `DROP TABLE` is the final piece to make `DROP TABLE` fully reliable. Dropping multiple tables is crash-safe. See Atomic DDL for more information.

Examples

```
DROP TABLE Employees, Customers;
```

Notes

Beware that `DROP TABLE` can drop both tables and sequences. This is mainly done to allow old tools like mariadb-dump (previously mysqldump) to work with sequences.

See Partitioning Types Overview.

An introduction to the various partitioning strategies available in MariaDB, helping you choose the right method for your data distribution needs. For a complete list of partitioning types, see this page.

See Partitioning Limitations.

This page outlines constraints when using partitioning, such as the maximum number of partitions and restrictions on foreign keys and query cache usage.

See Partitions Files.

Learn how MariaDB stores partitioned tables on the filesystem, typically creating separate .ibd files for each partition when using InnoDB.

See Partitions Metadata.

Understand how to retrieve metadata about partitions using the `INFORMATION_SCHEMA.PARTITIONS` table to monitor row counts and storage usage.

This page is licensed: CC BY-SA / Gnu FDL

Partitioning Overview

In MariaDB, a table can be split in smaller subsets. Both data and indexes are partitioned.

Uses for Partitioning

There can be several reasons to use this feature:

- If you often need to delete a large set of rows, such as all rows for a given year, using partitions can help, as dropping a partition with many rows is very fast, while deleting a lot of rows can be very slow.
- Very large tables and indexes can be slow even with optimized queries. But if the target table is partitioned, queries that read a small number of partitions can be much faster. However, this means that the queries have to be written carefully in order to only access a given set of partitions.
- Partitioning allows one to distribute files over multiple storage devices. For example, we can have historical data on slower, larger disks (historical data are not supposed to be frequently read); and current data can be on faster disks, or SSD devices.
- In case we separate historical data from recent data, we will probably need to take regular backups of one partition, not the whole table.

Partitioning Types

When partitioning a table, the use should decide:

- a partitioning type;
- a partitioning expression.

A partitioning type is the method used by MariaDB to decide how rows are distributed over existing partitions. Choosing the proper partitioning type is important to distribute rows over partitions in an efficient way.

With some partitioning types, a partitioning expression is also required. A partitioning function is an SQL expression returning an integer or temporal value, used to determine which partition will contain a given row. The partitioning expression is used for all reads and writes on involving the partitioned table, thus it should be fast.

MariaDB supports the following partitioning types:

- RANGE
- LIST
- RANGE COLUMNS and LIST COLUMNS
- HASH
- LINEAR HASH
- KEY
- LINEAR KEY
- SYSTEM_TIME

Enabling Partitioning

By default, MariaDB permits partitioning. You can determine this by using the SHOW PLUGINS statement, for example:

```
SHOW PLUGINS;
...
| Aria                          | ACTIVE   | STORAGE ENGINE     | NULL    | GPL     |
| FEEDBACK                      | DISABLED | INFORMATION SCHEMA | NULL    | GPL     |
| partition                     | ACTIVE   | STORAGE ENGINE     | NULL    | GPL     |
+-------------------------------+----------+--------------------+---------+---------+
```

If partition is listed as DISABLED:

```
| partition                     | DISABLED | STORAGE ENGINE     | NULL    | GPL     |
+-------------------------------+----------+--------------------+---------+---------+
```

MariaDB has either been built without partitioning support, or has been started with the –skip-partition option, or one of its variants:

```
--skip-partition
--disable-partition
--partition=OFF
```

and you will not be able to create partitions.

Using Partitions

It is possible to create a new partitioned table using CREATE TABLE.

ALTER TABLE allows one to:

- Partition an existing table;
- Remove partitions from a partitioned table (with all data in the partition);
- Add/remove partitions, or reorganize them, as long as the partitioning function allows these operations (see below);
- Exchange a partition with a table;
- Perform administrative operations on some or all partitions (analyze, optimize, check, repair).

Adding Partitions

```
ADD PARTITION [IF NOT EXISTS] (partition_definition)
```

`ADD PARTITION` can be used to add partitions to an existing table:

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

ALTER TABLE t1 ADD PARTITION (
  PARTITION p4 VALUES LESS THAN (2017),
  PARTITION p5 VALUES LESS THAN (2018)
);
```

With RANGE partitions, it is only possible to add a partition to the high end of the range, not the low end. For example, the following results in an error:

```
ALTER TABLE t1 ADD PARTITION (
  PARTITION p0a VALUES LESS THAN (2012)
);
ERROR 1493 (HY000): VALUES LESS THAN value must be strictly increasing for each partition
```

You can work around this by using REORGANIZE PARTITION to split the partition instead. See Splitting Partitions.

Coalescing Partitions

```
COALESCE PARTITION number
```

ALTER TABLE is used to reduce the number of `HASH` or `KEY` partitions by the specified number. For example, given the following table with 5 partitions:

```
CREATE OR REPLACE TABLE t1 (v1 INT)
  PARTITION BY KEY (v1)
  PARTITIONS 5;
```

The following statement reduces the number of partitions by 2, leaving the table with 3 partitions:

```
ALTER TABLE t1 COALESCE PARTITION 2;
```

Converting Partitions to/from Tables

> **Note:**
>
> This feature is available from MariaDB 10.7.

```
CONVERT PARTITION partition_name TO TABLE tbl_name
CONVERT TABLE normal_table TO partition_definition
```

ALTER TABLE can be used to convert partitions in an existing table to a standalone table:

```
CREATE OR REPLACE TABLE t1 (
   dt DATETIME NOT NULL
 )
   ENGINE = InnoDB
   PARTITION BY RANGE (YEAR(dt))
   (
   PARTITION p0 VALUES LESS THAN (2013),
   PARTITION p1 VALUES LESS THAN (2014),
   PARTITION p2 VALUES LESS THAN (2015),
   PARTITION p3 VALUES LESS THAN (2016)
 );

INSERT INTO t1 VALUES ('2013-11-11'),('2014-11-11'),('2015-11-11');

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-11 00:00:00 |
| 2014-11-11 00:00:00 |
| 2015-11-11 00:00:00 |
+---------------------+

ALTER TABLE t1 CONVERT PARTITION p3 TO TABLE t2;

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-11 00:00:00 |
| 2014-11-11 00:00:00 |
+---------------------+

SELECT * FROM t2;
+--------------+
| dt           |
+--------------+
| 2015-11-11 00:00:00 |
+---------------------+

SHOW CREATE TABLE t1\G
*************************** 1. row ***************************
       TABLE: t1
CREATE TABLE: CREATE TABLE `t1` (
  `dt` datetime NOT NULL
) ENGINE=InnoDB DEFAULT CHARSET=latin1 COLLATE=latin1_swedish_ci
 PARTITION BY RANGE (year(`dt`))
(PARTITION `p0` VALUES LESS THAN (2013) ENGINE = InnoDB,
 PARTITION `p1` VALUES LESS THAN (2014) ENGINE = InnoDB,
 PARTITION `p2` VALUES LESS THAN (2015) ENGINE = InnoDB)

SHOW CREATE TABLE t2\G
*************************** 1. row ***************************
       TABLE: t2
CREATE TABLE: CREATE TABLE `t2` (
  `dt` datetime NOT NULL
) ENGINE=InnoDB DEFAULT CHARSET=latin1 COLLATE=latin1_swedish_ci
```

`CONVERT TABLE` does the reverse, converting a table into a partition:

```
ALTER TABLE t1 CONVERT TABLE t2 TO PARTITION p3 VALUES LESS THAN (2016);

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-11 00:00:00 |
| 2014-11-11 00:00:00 |
| 2015-11-11 00:00:00 |
+---------------------+
3 rows in set (0.001 sec)

SELECT * FROM t2;
ERROR 1146 (42S02): Table 'test.t2' doesn't exist

SHOW CREATE TABLE t1\G
*************************** 1. row ***************************
       TABLE: t1
CREATE TABLE: CREATE TABLE `t1` (
  `dt` datetime NOT NULL
) ENGINE=InnoDB DEFAULT CHARSET=latin1 COLLATE=latin1_swedish_ci
 PARTITION BY RANGE (year(`dt`))
(PARTITION `p0` VALUES LESS THAN (2013) ENGINE = InnoDB,
 PARTITION `p1` VALUES LESS THAN (2014) ENGINE = InnoDB,
 PARTITION `p2` VALUES LESS THAN (2015) ENGINE = InnoDB,
 PARTITION `p3` VALUES LESS THAN (2016) ENGINE = InnoDB)
```

CONVERT TABLE ... WITH / WITHOUT VALIDATION

> **Note:**
>
> This feature is available from MariaDB 11.4.

When converting tables to a partition, validation is performed on each row to ensure it meets the partition requirements. This can be very slow in the case of larger tables. It is possible to disable this validation by specifying the `WITHOUT VALIDATION` option.

```
CONVERT TABLE normal_table TO partition_definition [{WITH | WITHOUT} VALIDATION]
```

`WITH VALIDATION` will result in the validation being performed, and is the default behaviour.

An alternative to convert partitions to tables is to use ALTER TABLE EXCHANGE PARTITION. This requires having to manually do the following steps:

1. Create an empty table with the same structure as the partition.
2. Exchange the table with the partition.
3. Drop the empty partition.

For example:

```
CREATE OR REPLACE TABLE t1 (
   dt DATETIME NOT NULL
 )
   ENGINE = InnoDB
   PARTITION BY RANGE (YEAR(dt))
   (
   PARTITION p0 VALUES LESS THAN (2013),
   PARTITION p1 VALUES LESS THAN (2014),
   PARTITION p2 VALUES LESS THAN (2015),
   PARTITION p3 VALUES LESS THAN (2016)
 );

INSERT INTO t1 VALUES ('2013-11-11'),('2014-11-11'),('2015-11-11');

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-11 00:00:00 |
| 2014-11-11 00:00:00 |
| 2015-11-11 00:00:00 |
+---------------------+

CREATE OR REPLACE TABLE t2 LIKE t1;

ALTER TABLE t2 REMOVE PARTITIONING;

ALTER TABLE t1 EXCHANGE PARTITION p3 WITH TABLE t2;

ALTER TABLE t1 DROP PARTITION p3;

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-11 00:00:00 |
| 2014-11-11 00:00:00 |
+---------------------+

SELECT * FROM t2;
+--------------+
| dt           |
+--------------+
| 2015-11-11 00:00:00 |
+---------------------+

SHOW CREATE TABLE t1\G
*************************** 1. row ***************************
       TABLE: t1
CREATE TABLE: CREATE TABLE `t1` (
  `dt` datetime NOT NULL
) ENGINE=InnoDB DEFAULT CHARSET=latin1 COLLATE=latin1_swedish_ci
 PARTITION BY RANGE (year(`dt`))
(PARTITION `p0` VALUES LESS THAN (2013) ENGINE = InnoDB,
 PARTITION `p1` VALUES LESS THAN (2014) ENGINE = InnoDB,
 PARTITION `p2` VALUES LESS THAN (2015) ENGINE = InnoDB)

SHOW CREATE TABLE t2\G
*************************** 1. row ***************************
       TABLE: t2
CREATE TABLE: CREATE TABLE `t2` (
  `dt` datetime NOT NULL
) ENGINE=InnoDB DEFAULT CHARSET=latin1 COLLATE=latin1_swedish_ci
```

Similarly, to do the reverse and convert a table into a partition `[ALTER TABLE](#pg-ence-sql-statements-data-definition-alter-alter-table-readme-a2aa59e4) ... EXCHANGE PARTITION` can also be used, with the following manual steps required:

- create the partition
- exchange the partition with the table
- drop the old table:

For example:

```
ALTER TABLE t1 ADD PARTITION (PARTITION p3 VALUES LESS THAN (2016));

ALTER TABLE t1 EXCHANGE PARTITION p3 WITH TABLE t2;

DROP TABLE t2;

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-11 00:00:00 |
| 2014-11-11 00:00:00 |
| 2015-11-11 00:00:00 |
+---------------------+

SHOW CREATE TABLE t1\G
*************************** 1. row ***************************
       TABLE: t1
CREATE TABLE: CREATE TABLE `t1` (
  `dt` datetime NOT NULL
) ENGINE=InnoDB DEFAULT CHARSET=latin1 COLLATE=latin1_swedish_ci
 PARTITION BY RANGE (year(`dt`))
(PARTITION `p0` VALUES LESS THAN (2013) ENGINE = InnoDB,
 PARTITION `p1` VALUES LESS THAN (2014) ENGINE = InnoDB,
 PARTITION `p2` VALUES LESS THAN (2015) ENGINE = InnoDB,
 PARTITION `p3` VALUES LESS THAN (2016) ENGINE = InnoDB)
```

Dropping Partitions

```
DROP PARTITION [IF EXISTS] partition_names
```

ALTER TABLE DROP PARTITIONcan be used to drop specific partitions (and discard all data within the specified partitions) for RANGE and LIST partitions. It cannot be used on HASH or KEY partitions. To rather remove all partitioning, while leaving the data unaffected, see Removing Partitioning.

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

INSERT INTO t1 VALUES ('2012-11-15');
SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2012-11-15 00:00:00 |
+---------------------+

ALTER TABLE t1 DROP PARTITION p0;

SELECT * FROM t1;
Empty set (0.002 sec)
```

Exchanging Partitions

CURRENT

```
EXCHANGE PARTITION partition_name WITH TABLE tbl_name [{WITH | WITHOUT} VALIDATION]
```

< 11.4

```
EXCHANGE PARTITION partition_name WITH TABLE tbl_name
```

`ALTER TABLE t1 EXCHANGE PARTITION p1 WITH TABLE t2` allows to exchange a partition or subpartition with another table.

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014)
);

CREATE OR REPLACE TABLE t2 (
  dt DATETIME NOT NULL
) ENGINE = InnoDB;

INSERT INTO t1 VALUES ('2012-01-01'),('2013-01-01');

INSERT INTO t2 VALUES ('2013-02-02');

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2012-01-01 00:00:00 |
| 2013-01-01 00:00:00 |
+---------------------+

SELECT * FROM t2;
+--------------+
| dt           |
+--------------+
| 2013-02-02 00:00:00 |
+---------------------+

ALTER TABLE t1 EXCHANGE PARTITION p1 WITH TABLE t2;

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2012-01-01 00:00:00 |
| 2013-02-02 00:00:00 |
+---------------------+

SELECT * FROM t2;
+--------------+
| dt           |
+--------------+
| 2013-01-01 00:00:00 |
+---------------------+
```

The following requirements must be met:

- Table t1 must be partitioned, and table t2 cannot be partitioned.
- Table t2 cannot be a temporary table.
- Table t1 and t2 must otherwise be identical.
- Any existing row in t2 must match the conditions for storage in the exchanged partition p1 unless, from MariaDB 11.4, the `WITHOUT VALIDATION` option is specified.

By default, MariaDB performs the validation to see that each row meets the partition requirements, and the statement fails if a row does not fit.

This attempted exchange fails, as the value is already in t2, and `2015-05-05` is outside of the partition conditions:

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014)
);

CREATE OR REPLACE TABLE t2 (
  dt DATETIME NOT NULL
) ENGINE = InnoDB;

INSERT INTO t1 VALUES ('2012-02-02'),('2013-03-03');

INSERT INTO t2 VALUES ('2015-05-05');

ALTER TABLE t1 EXCHANGE PARTITION p1 WITH TABLE t2;
```

```
ERROR 1526 (HY000): Table has no partition for value 0
```

WITH / WITHOUT VALIDATION

> **Note:**
>
> This feature is available from MariaDB 11.4.

This validation is performed for each row, and can be very slow in the case of larger tables. It is possible to disable this validation by specifying the `WITHOUT VALIDATION` option:

```
ALTER TABLE t1 EXCHANGE PARTITION p1 WITH TABLE t2 WITHOUT VALIDATION;
```

```
Query OK, 0 rows affected (0.048 sec)
```

`WITH VALIDATION` results in the validation being performed, and is the default behavior.

Removing Partitioning

```
REMOVE PARTITIONING
```

ALTER TABLE REMOVE PARTITIONING removes all partitioning from the table, while leaving the data unaffected. To rather drop a particular partition (and discard all of its data), see Dropping Partitions.

```
ALTER TABLE t1 REMOVE PARTITIONING;
```

Reorganizing Partitions

```
REORGANIZE PARTITION [partition_names INTO (partition_definitions)]
```

Reorganizing partitions allows one to adjust existing partitions, without losing data. Specifically, the statement can be used for:

- Splitting an existing partition into multiple partitions.
- Merging a number of existing partitions into a new, single, partition.
- Changing the ranges for a subset of existing partitions defined using `VALUES LESS THAN`.
- Changing the value lists for a subset of partitions defined using `VALUES I`.

- Renaming partitions.

Splitting Partitions

An existing partition can be split into multiple partitions. This can also be used to add a new partition at the low end of a RANGE partition (which is not possible by Adding Partitions).

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

ALTER TABLE t1 REORGANIZE PARTITION p0 INTO (
    PARTITION p0a VALUES LESS THAN (2012),
    PARTITION p0b VALUES LESS THAN (2013)
);
```

Similarly, if `MAXVALUE` binds the high end:

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016),
  PARTITION p4 VALUES LESS THAN MAXVALUE
);

ALTER TABLE t1 REORGANIZE PARTITION p4 INTO (
    PARTITION p4 VALUES LESS THAN (2017),
    PARTITION p5 VALUES LESS THAN MAXVALUE
);
```

Merging Partitions

A number of existing partitions can be merged into a new partition, for example:

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

ALTER TABLE t1 REORGANIZE PARTITION p2,p3 INTO (
    PARTITION p2 VALUES LESS THAN (2016)
);
```

Changing Ranges

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

ALTER TABLE t1 REORGANIZE PARTITION p3 INTO (
  PARTITION p3 VALUES LESS THAN (2017)
);
```

Renaming Partitions

The ALTER TABLE REORGANIZE PARTITION statement can also be used for renaming partitions. Note that this creates a copy of the partition:

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

ALTER TABLE t1 REORGANIZE PARTITION p3 INTO (
  PARTITION p3_new VALUES LESS THAN (2016)
);
```

Truncating Partitions

```
TRUNCATE PARTITION partition_names
```

`[ALTER TABLE](#pg-ence-sql-statements-data-definition-alter-alter-table-readme-a2aa59e4) ... TRUNCATE PARTITION`

ALTER TABLE TRUNCATE PARTITION removes all data from the specified partition/s, leaving the table and partition structure unchanged. Partitions don’t need to be contiguous:

```
CREATE OR REPLACE TABLE t1 (
  dt DATETIME NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE (YEAR(dt))
  (
  PARTITION p0 VALUES LESS THAN (2013),
  PARTITION p1 VALUES LESS THAN (2014),
  PARTITION p2 VALUES LESS THAN (2015),
  PARTITION p3 VALUES LESS THAN (2016)
);

INSERT INTO t1 VALUES ('2012-11-01'),('2013-11-02'),('2014-11-03'),('2015-11-04');

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2012-11-01 00:00:00 |
| 2013-11-02 00:00:00 |
| 2014-11-03 00:00:00 |
| 2015-11-04 00:00:00 |
+---------------------+

ALTER TABLE t1 TRUNCATE PARTITION p0,p2;

SELECT * FROM t1;
+--------------+
| dt           |
+--------------+
| 2013-11-02 00:00:00 |
| 2015-11-04 00:00:00 |
+---------------------+
```

Analyzing Partitions

Similar to ANALYZE TABLE, key distributions for specific partitions can also be analyzed and stored, for example:

```
ALTER TABLE t1 ANALYZE PARTITION p0,p1,p3;
+---------+---------+----------+----------+
| Table   | Op      | Msg_type | Msg_text |
+---------+---------+----------+----------+
| test.t1 | analyze | status   | OK       |
+---------+---------+----------+----------+
```

Checking Partitions

```
CHECK PARTITION {ALL | PARTITION [,partition2 ...]}
```

Similar to CHECK TABLE, specific partitions can be checked for errors, for example:

```
ALTER TABLE t1 CHECK PARTITION p1,p3;
+---------+-------+----------+----------+
| Table   | Op    | Msg_type | Msg_text |
+---------+-------+----------+----------+
| test.t1 | check | status   | OK       |
+---------+-------+----------+----------+
```

The `ALL` keyword can be used in place of the list of partition names, and the check operation are performed on all partitions.

Repairing Partitions

```
REPAIR PARTITION {ALL | partition [,partition2 ...]} [QUICK] [EXTENDED]
```

Similar to REPAIR TABLE, specific partitions can be repaired:

```
ALTER TABLE t1 REPAIR PARTITION p0,p3;
+---------+--------+----------+----------+
| Table   | Op     | Msg_type | Msg_text |
+---------+--------+----------+----------+
| test.t1 | repair | status   | OK       |
+---------+--------+----------+----------+
```

As with REPAIR TABLE, the `QUICK` and `EXTENDED` options are available. However, the `USE_FRM` option cannot be used with this statement on a partitioned table.

`REPAIR PARTITION` fails if there are duplicate key errors. `ALTER IGNORE TABLE ... REPAIR PARTITION` can be used in this case.

The `ALL` keyword can be used in place of the list of partition names, and the repair operation are performed on all partitions.

Optimizing Partitions

```
OPTIMIZE PARTITION {ALL | PARTITION [,partition2 ...]}
```

Similar to OPTIMIZE TABLE, specific partitions can be checked for errors:

```
ALTER TABLE t1 OPTIMIZE PARTITION p0,p3;
+---------+----------+----------+----------+
| Table   | Op       | Msg_type | Msg_text |
+---------+----------+----------+----------+
| test.t1 | optimize | status   | OK       |
+---------+----------+----------+----------+
```

`OPTIMIZE PARTITION` does not support per-partition optimization on InnoDB tables, and will issue a warning and cause the entire table to rebuilt and analyzed. `ALTER TABLE ... REBUILD PARTITION` and `ALTER TABLE ... ANALYZE PARTITION` can be used instead.

The `ALL` keyword can be used in place of the list of partition names, and the optimize operation are performed on all partitions.

Partitioning for Specific Storage Engines

Some MariaDB storage engines allow more interesting uses for partitioning.

The MERGE storage engine allows one to:

- Treat a set of identical defined MyISAM tables as one.
- A MyISAM table can be in many different `MERGE` sets and also used separately.

SPIDER allows one to:

- Move partitions of the same table on different servers. In this way, the workload can be distributed on more physical or virtual machines (data sharding).
- All partitions of a `SPIDER` table can also live on the same machine. In this case there are a small overhead (`SPIDER` uses connections to localhost), but queries that read multiple partitions will use parallel threads.

CONNECT allows one to:

- Build a table whose partitions are tables using different storage engines (like InnoDB, MyISAM, or even engines that do not support partitioning).
- Build an indexable, writeable table on several data files. These files can be in different formats.

Partition Pruning and Selection

When a `WHERE` clause is related to the partitioning expression, the optimizer knows which partitions are relevant for the query. Other partitions will not be read. This optimization is called *partition pruning*.

EXPLAIN PARTITIONS can be used to know which partitions are read for a given query. A column called `partitions` will contain a comma-separated list of the accessed partitions. For example:

```
EXPLAIN PARTITIONS SELECT * FROM orders WHERE id < 15000000;
+------+-------------+--------+------------+-------+---------------+---------+---------+------+------+---
----------+
| id   | select_type | table  | partitions | type  | possible_keys | key     | key_len | ref  | rows |
Extra       |
+------+-------------+--------+------------+-------+---------------+---------+---------+------+------+---
----------+
|    1 | SIMPLE      | orders | p0,p1      | range | PRIMARY       | PRIMARY | 4       | NULL |    2 |
Using where |
+------+-------------+--------+------------+-------+---------------+---------+---------+------+------+---
----------+
```

Sometimes the WHERE clause does not contain the necessary information to use partition pruning, or the optimizer cannot infer this information. However, we may know which partitions are relevant for the query. We can force MariaDB to only access the specified partitions by adding a `PARTITION` clause. This feature is called *partition selection*. For example:

```
SELECT * FROM orders PARTITION (p3) WHERE user_id = 50;
SELECT * FROM orders PARTITION (p2,p3) WHERE user_id >= 40;
```

The `PARTITION` clause is supported for all DML statements:

- SELECT
- INSERT
- UPDATE
- DELETE
- REPLACE

Partition Pruning and Triggers

In general, partition pruning is applied to statements contained in triggers.

However, note that if a `BEFORE INSERT` or `BEFORE UPDATE` trigger is defined on a table, MariaDB doesn't know in advance if the columns used in the partitioning expression are changed. For this reason, it is forced to lock all partitions.

Partition Maintenance

Maintenance Instructions

You can perform several maintenance tasks on partitioned tables using standard SQL statements or specific `ALTER TABLE` extensions.

Table-Level Maintenance

For general maintenance, MariaDB supports the following statements on partitioned tables just as it does for non-partitioned tables:

- `CHECK TABLE`
- `OPTIMIZE TABLE`
- `ANALYZE TABLE`
- `REPAIR TABLE`

Partition-Specific Operations

To target one or more specific partitions rather than the entire table, use the `ALTER TABLE` extensions listed below. In the SQL syntaxes below, *`partition_names`* is a comma-separated list of partitions, like `p0, p1, p2`.

> **Note:**
>
> For an operation to be performed on all partitions, you can use the `ALL` keyword instead of specifying all the partitions in a comma-separated list. Example:
>
> ```
> ALTER TABLE table_name REBUILD PARTITION ALL
> ```

Rebuilding Partitions

Use this to defragment a partition. This operation drops all records in the partition and re-inserts them:

```
ALTER TABLE table_name REBUILD PARTITION partition_names
```

Optimizing Partitions

If you have deleted many rows or modified variable-length columns (such as `VARCHAR`, `BLOB`, or `TEXT`), use this statement to reclaim unused space and defragment the data file:

```
ALTER TABLE table_name OPTIMIZE PARTITION partition_names
```

> **Note:**
>
> Some storage engines, including `InnoDB`, do not support per-partition optimization. When you run `OPTIMIZE PARTITION` on an `InnoDB` table, MariaDB rebuilds and analyzes the entire table instead.

Analyzing Partitions

Use this to read and store the key distributions for specific partitions:

```
ALTER TABLE table_name ANALYZE PARTITION partition_names
```

Repairing Partitions

Use this to fix corrupted partitions:

```
ALTER TABLE table_name REPAIR PARTITION partition_names
```

Checking Partitions

You can verify the integrity of data and indexes within a partition:

```
ALTER TABLE table_name CHECK PARTITION partition_names
```

Truncating Partitions

To remove all rows from specific partitions while keeping the table structure, use the `TRUNCATE PARTITION` clause:

```
ALTER TABLE table_name TRUNCATE PARTITION partition_names
```

Reorganizing Partitions

Reorganizing partitions isn't just maintenance, but it can help with making future maintenance easier. Use the following statement to change the structure of existing partitions without losing data. This is particularly useful for splitting a partition that contains a `MAXVALUE` range into a new specific range and a new `MAXVALUE` partition. Use the following syntax:

```
ALTER TABLE table_name REORGANIZE PARTITION partition_names INTO (PARTITION partition_definition, ...)
```

Example: If you have a partition `p_future` defined as `VALUES LESS THAN MAXVALUE`, you can split it to add a specific range for the year 2026:

```
ALTER TABLE tbl REORGANIZE PARTITION p_future INTO (PARTITION p_2026 VALUES LESS THAN (2027), PARTITION
p_future VALUES LESS THAN MAXVALUE)
```

Best Practices and Considerations

When managing partitioned tables, follow these guidelines to ensure optimal performance and maintainability.

Managing Time-Series Data

Partitioning is most effective for tables containing time-series data where you periodically remove old records.

- Efficient Deletion: Use `DROP PARTITION` instead of `DELETE` to remove expired data. This is a metadata operation and is significantly faster than row-by-row deletion.
- The Future Partition: When using `RANGE` partitioning, define a "future" partition using `VALUES LESS THAN MAXVALUE`. To add a new specific range, use `REORGANIZE PARTITION` to split the "future" partition into a new range and a new `MAXVALUE` partition. See this section for the syntax.
- The Start Partition: Consider creating a small, empty "start" partition (for example, `VALUES LESS THAN (0)`) to catch `NULL` values or invalid data. Because the partition pruner often scans the first partition by default, keeping it empty improves query efficiency.

Performance and Scale

- Table Size: Partitioning generally provides noticeable benefits only for tables with more than one million rows.
- Partition Limits: Aim to keep the number of partitions below 50. While MariaDB supports up to 8192 partitions, high partition counts can increase the time required for the server to open the table or perform status checks.

- Index Efficiency: Partitioning is not a substitute for proper indexing. Point queries (finding a single row) are often just as fast with a proper index on a non-partitioned table.

Partitioning Types

See Partitioning Types Overview.

An introduction to the various partitioning strategies available in MariaDB, helping you choose the right method for your data distribution needs.

See HASH Partitioning Type.

Learn about HASH partitioning, which distributes data based on a user-defined expression to ensure an even spread of rows across partitions.

See KEY Partitioning Type.

Understand KEY partitioning, similar to HASH but using MariaDB's internal hashing function on one or more columns to distribute data.

See LINEAR HASH Partitioning Type.

Explore LINEAR HASH partitioning, a variation of HASH that uses a powers-of-two algorithm for faster partition management at the cost of distribution.

See LINEAR KEY Partitioning Type.

Learn about LINEAR KEY partitioning, which combines the internal key hashing with a linear algorithm for efficient partition handling.

See LIST Partitioning Type.

Understand LIST partitioning, where rows are assigned to partitions based on whether a column value matches one in a defined list of values.

See RANGE COLUMNS and LIST COLUMNS Partitioning Types.

Discover these variants that allow partitioning based on multiple columns and non-integer types, offering greater flexibility than standard RANGE/LIST.

See RANGE Partitioning Type.

The RANGE partitioning type assigns rows to partitions based on whether column values fall within contiguous, non-overlapping ranges.

This page is licensed: CC BY-SA / Gnu FDL

Partitioning Types Overview

A partitioning type determines how a partitioned table's rows are distributed across partitions. Some partition types require the user to specify a partitioning expression that determines in which partition a row are stored.

The size of individual partitions depends on the partitioning type. Read and write performance are affected by the partitioning expression. Therefore, these choices should be made carefully.

Partitioning Types

MariaDB supports the following partitioning types:

- RANGE

- LIST
- RANGE COLUMNS and LIST COLUMNS
- HASH
- LINEAR HASH
- KEY
- LINEAR KEY
- SYSTEM_TIME

See Also

HASH Partitioning Type

Syntax

```
PARTITION BY HASH (partitioning_expression)
[PARTITIONS(number_of_partitions)]
```

Description

`HASH` partitioning is a form of partitioning in which the server takes care of the partition in which to place the data, ensuring an even distribution among the partitions.

It requires a column value, or an expression based on a column value, which is hashed, as well as the number of partitions into which to divide the table.

- *`partitioning_expression`* needs to return a non-constant, deterministic integer. It is evaluated for each insert and update, so overly complex expressions can lead to performance issues. A hashing function operating on a single column, and where the value changes consistently with the column value, allows for easy pruning on ranges of partitions, and is usually a better choice. For this reason, using multiple columns in a hashing expression is not usually recommended.
- *`number_of_partitions`* is a positive integer specifying the number of partitions into which to divide the table. If the `PARTITIONS` clause is omitted, the default number of partitions is one.

Determining the Partition

To determine which partition to use, perform the following calculation:

```
MOD(partitioning_expression, number_of_partitions)
```

For example, if the expression is `TO_DAYS( datetime_column )` and the number of partitions is 5, inserting a datetime value of `'2023-11-15'` would determine the partition as follows:

- `TO_DAYS('2023-11-15')` gives a value of 739204.
- `MOD(739204,5)` returns 4, so the 4th partition is used.

`HASH` partitioning makes use of the modulus of the hashing function's value. The LINEAR HASH partitioning type is similar, using a powers-of-two algorithm. Data is more likely to be evenly distributed over the partitions than with the `LINEAR HASH` partitioning type; however, adding, dropping, merging and splitting partitions is much slower.

Examples

```
CREATE OR REPLACE TABLE t1 (c1 INT, c2 DATETIME)
  PARTITION BY HASH(TO_DAYS(c2))
  PARTITIONS 5;
```

Using the Information Schema PARTITIONS Table for more information:

```
INSERT INTO t1 VALUES (1,'2023-11-15');

SELECT PARTITION_NAME,TABLE_ROWS FROM INFORMATION_SCHEMA.PARTITIONS
  WHERE TABLE_SCHEMA='test' AND TABLE_NAME='t1';
+----------------+------------+
| PARTITION_NAME | TABLE_ROWS |
+----------------+------------+
| p0             |          0 |
| p1             |          0 |
| p2             |          0 |
| p3             |          0 |
| p4             |          1 |
+----------------+------------+
```

See Also

- Partition Maintenance for suggestions on using partitions

KEY Partitioning Type

Syntax

CURRENT

```
PARTITION BY KEY
[ALGORITHM={MYSQL51|MYSQL55|BASE31|CRC32C|XXH32|XXH3}]
([column_names])
[PARTITIONS (number_of_partitions)]
```

- `MYSQL51` and `MYSQL55` are existing algorithms, with `MYSQL55` being the default, also used by default before 12.3
- `CRC32C`, `XXH32`, and `XXH3` use the established hash algorithms of the same names. These are recommended algorithms to use.
- `BASE31` uses a base-31 representation of the bytes and serves as a simple baseline that is more evenly distributed than `MYSQL51` or `MYSQL55` for simple sequential data.

< 12.3

```
PARTITION BY KEY ([column_names])
[PARTITIONS (number_of_partitions)]
```

Description

Partitioning by key is a type of partitioning that is similar to and can be used in a similar way as partitioning by hash.

`KEY` takes an optional list of *`column_names`*, and the hashing function is given by the server.

Compared to `HASH` partitioning, `KEY` partitioning distributes data using a preset hash algorithms on the specified columns, rather than an expression specified by the user.

If no *column_names* are specified, the table's primary key is used if present, or not null unique key if no primary key is present. If neither of these keys are present, not specifying any *column_names* will result in an error:

```
 ERROR 1488 (HY000): Field in list of fields for partition function not found in table
```

Unlike other partitioning types, columns used for partitioning by `KEY` are not limited to integer or `NULL` values.

`KEY` partitions do not support column index prefixes. Any columns in the partitioning key that make use of column prefixes are not used.

Examples

```
CREATE OR REPLACE TABLE t1 (v1 INT)
  PARTITION BY KEY (v1)
  PARTITIONS 2;
```

```
CREATE OR REPLACE TABLE t1 (v1 INT, v2 INT)
  PARTITION BY KEY (v1,v2)
  PARTITIONS 2;
```

```
CREATE OR REPLACE TABLE t1 (
    id INT NOT NULL PRIMARY KEY,
    name VARCHAR(5)
)
PARTITION BY KEY()
PARTITIONS 2;
```

```
CREATE OR REPLACE TABLE t1 (
    id INT NOT NULL UNIQUE KEY,
    name VARCHAR(5)
)
PARTITION BY KEY()
PARTITIONS 2;
```

The unique key must be `NOT NULL`:

```
CREATE OR REPLACE TABLE t1 (
    id INT NULL UNIQUE KEY,
    name VARCHAR(5)
)
PARTITION BY KEY()
PARTITIONS 2;
ERROR 1488 (HY000): Field in list of fields for partition function not found in table
```

`KEY` requires *column_values* if no primary key or not null unique key is present:

```
CREATE OR REPLACE TABLE t1 (
    id INT NULL UNIQUE KEY,
    name VARCHAR(5)
)
PARTITION BY KEY()
PARTITIONS 2;
ERROR 1488 (HY000): Field in list of fields for partition function not found in table
```

```
CREATE OR REPLACE TABLE t1 (
    id INT NULL UNIQUE KEY,
    name VARCHAR(5)
)
PARTITION BY KEY(name)
PARTITIONS 2;
```

Primary key columns with index prefixes are silently ignored, so the following two queries are equivalent:

```
CREATE OR REPLACE TABLE t1 (
    a VARCHAR(10),
    b VARCHAR(10),
    c VARCHAR(10),
    PRIMARY KEY (a(5), b, c(5))
) PARTITION BY KEY() PARTITIONS 2;

CREATE OR REPLACE TABLE t1 (
    a VARCHAR(10),
    b VARCHAR(10),
    c VARCHAR(10),
    PRIMARY KEY (b)
) PARTITION BY KEY() PARTITIONS 2;
```

`a(5)` and `c(5)` are silently ignored in the former.

If all columns use index prefixes, the statement fails with a slightly misleading error:

```
CREATE OR REPLACE TABLE t1 (
    a VARCHAR(10),
    b VARCHAR(10),
    c VARCHAR(10),
    PRIMARY KEY (a(5), b(5), c(5))
) PARTITION BY KEY() PARTITIONS 2;
ERROR 1503 (HY000): A PRIMARY KEY must include all columns in the table's partitioning function
```

LINEAR HASH Partitioning Type

Syntax

```
PARTITION BY LINEAR HASH (partitioning_expression)
[PARTITIONS(number_of_partitions)]
```

Description

`LINEAR HASH` partitioning is a form of partitioning, similar to HASH partitioning, in which the server takes care of the partition in which to place the data, ensuring a relatively even distribution among the partitions.

`LINEAR HASH` partitioning makes use of a powers-of-two algorithm, while `HASH` partitioning uses the modulus of the hashing function's value. Adding, dropping, merging and splitting partitions is much faster than with the HASH partitioning type, however, data is less likely to be evenly distributed over the partitions.

Example

```
CREATE OR REPLACE TABLE t1 (c1 INT, c2 DATETIME)
  PARTITION BY LINEAR HASH(TO_DAYS(c2))
  PARTITIONS 5;
```

This page is licensed: CC BY-SA / Gnu FDL

LINEAR KEY Partitioning Type

Syntax

> **CURRENT**

```
PARTITION BY LINEAR KEY [ALGORITHM={MYSQL51|MYSQL55|BASE31|CRC32C|XXH32|XXH3}]
([column_names])
[PARTITIONS (number_of_partitions)]
```

For a description of the different `ALGORITHM` types, see KEY Partitioning.

< 12.3

```
PARTITION BY LINEAR KEY ([column_names])
[PARTITIONS (number_of_partitions)]
```

Description

`LINEAR KEY` partitioning is a form of partitioning, similar to KEY partitioning.

`LINEAR KEY` partitioning makes use of a powers-of-two algorithm, while `KEY` partitioning uses modulo arithmetic to determine the partition number.

Adding, dropping, merging and splitting partitions is much faster than with the KEY partitioning type; however, data is less likely to be evenly distributed over the partitions.

Example

```
CREATE OR REPLACE TABLE t1 (v1 INT)
  PARTITION BY LINEAR KEY (v1)
  PARTITIONS 2;
```

This page is licensed: CC BY-SA / Gnu FDL

LIST Partitioning Type

`LIST` partitioning is conceptually similar to RANGE partitioning. In both cases you decide a partitioning expression (a column, or a slightly more complex calculation) and use it to determine which partitions will contain each row. However, with the `RANGE` type, partitioning is done by assigning a range of values to each partition. With the `LIST` type, we assign a set of values to each partition. This is usually preferred if the partitioning expression can return a limited set of values.

A variant of this partitioning method, LIST COLUMNS, allows us to use multiple columns and more datatypes.

Syntax

The last part of a CREATE TABLE statement can be the definition of the new table's partitions. In the case of `LIST` partitioning, the syntax is as follows:

```
PARTITION BY LIST (partitioning_expression)
(
    PARTITION partition_name VALUES IN (value_list),
    [ PARTITION partition_name VALUES IN (value_list), ... ]
        [ PARTITION partition_name DEFAULT ]
)
```

`PARTITION BY LIST` indicates that the partitioning type is `LIST`.

The *`partitioning_expression`* is an SQL expression that returns a value from each row. In the simplest cases, it is a column name. This value is used to determine which partition should contain a row.

`partition_name` is the name of a partition.

value_list is a list of values. If *partitioning_expression* returns one of these values, the row are stored in this partition. If we try to insert something that does not belong to any of these value lists, the row are rejected with an error.

The DEFAULT partition catches all records which do not fit into other partitions.

Use Cases

LIST partitioning can be useful when we have a column that can only contain a limited set of values. Even in that case, RANGE partitioning could be used instead; but LIST partitioning allows us to equally distribute the rows by assigning a proper set of values to each partition.

Example

```
CREATE OR REPLACE TABLE t1 (
  num TINYINT(1) NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY LIST (num) (
    PARTITION p0 VALUES IN (0,1),
    PARTITION p1 VALUES IN (2,3),
    PARTITION p2 DEFAULT
  );
```

This page is licensed: CC BY-SA / Gnu FDL

RANGE COLUMNS and LIST COLUMNS Partitioning Types

RANGE COLUMNS and LIST COLUMNS are variants of, respectively, RANGE and LIST. With these partitioning types, there is not a single partitioning expression; instead, a list of one or more columns is accepted. The following rules apply:

- The list can contain one or more columns.
- Columns can be of any integer, string, DATE, and DATETIME types.
- Only bare columns are permitted; no expressions.

All the specified columns are compared to the specified values to determine which partition should contain a specific row. See below for details.

Syntax

The last part of a CREATE TABLE statement can be definition of the new table's partitions. In the case of RANGE COLUMNS partitioning, the syntax is as follows:

```
PARTITION BY RANGE COLUMNS (col1, col2, ...)
(
    PARTITION partition_name VALUES LESS THAN (value1, value2, ...),
    [ PARTITION partition_name VALUES LESS THAN (value1, value2, ...), ... ]
)
```

The syntax for LIST COLUMNS is as follows:

```
PARTITION BY LIST COLUMNS (partitioning_expression)
(
    PARTITION partition_name VALUES IN (value1, value2, ...),
    [ PARTITION partition_name VALUES IN (value1, value2, ...), ... ]
        [ PARTITION partititon_name DEFAULT ]
)
```

partition_name is the name of a partition.

Comparisons

To determine which partition should contain a row, all specified columns are compared to each partition definition.

With `LIST COLUMNS`, a row matches a partition if all row values are identical to the specified values. At most one partition can match the row.

With `RANGE COLUMNS`, a row matches a partition if it is less than the specified value tuple in lexicographic order. The first partition that matches the row values are used.

The `DEFAULT` partition catches all records which do not fit in other partitions. Only one `DEFAULT` partition is allowed.

Examples

`RANGE COLUMNS` partition:

```
CREATE OR REPLACE TABLE t1 (
  date1 DATE NOT NULL,
  date2 DATE NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY RANGE COLUMNS (date1,date2) (
    PARTITION p0 VALUES LESS THAN ('2013-01-01', '1994-12-01'),
    PARTITION p1 VALUES LESS THAN ('2014-01-01', '1995-12-01'),
    PARTITION p2 VALUES LESS THAN ('2015-01-01', '1996-12-01')
);
```

`LIST COLUMNS` partition:

```
CREATE OR REPLACE TABLE t1 (
  num TINYINT(1) NOT NULL
)
  ENGINE = InnoDB
  PARTITION BY LIST COLUMNS (num) (
    PARTITION p0 VALUES IN (0,1),
    PARTITION p1 VALUES IN (2,3),
    PARTITION p2 DEFAULT
  );
```

This page is licensed: CC BY-SA / Gnu FDL

RANGE Partitioning Type

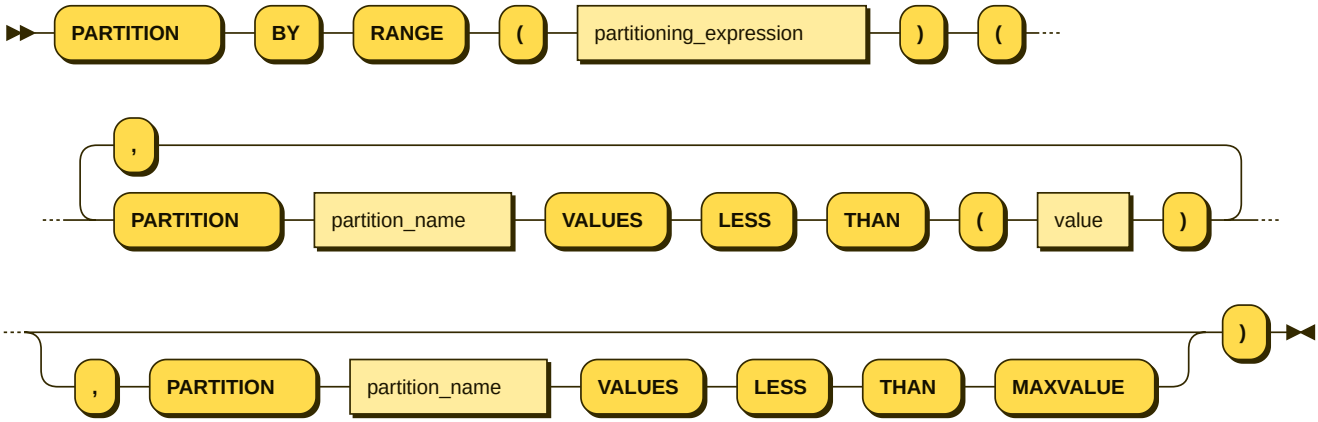
The `RANGE` partitioning type is used to assign each partition a range of values generated by the partitioning expression. Ranges must be ordered, contiguous and non-overlapping. The minimum value is always included in the first range. The highest value may or may not be included in the last range.

A variant of this partitioning method, RANGE COLUMNS, allows us to use multiple columns and more datatypes.

Syntax

The last part of a CREATE TABLE statement can be definition of the new table's partitions. In the case of `RANGE` partitioning, the syntax is the following:

```
PARTITION BY RANGE (partitioning_expression)
(
    PARTITION partition_name VALUES LESS THAN (value),
    [ PARTITION partition_name VALUES LESS THAN (value), ... ]
    [ PARTITION partition_name VALUES LESS THAN MAXVALUE ]
)
```



Railroad diagram of RANGE partitioning — equivalent to the BNF above

`PARTITION BY RANGE` indicates that the partitioning type is `RANGE`.

- *`partitioning_expression`* is an SQL expression that returns a value from each row. In the simplest cases, it is a column name. This value is used to determine which partition should contain a row.
- *`partition_name`* is the name of a partition.
- *`value`* indicates the upper bound for that partition. The values must be ascending. For the first partition, the lower limit is `NULL`. When trying to insert a row, if its value is higher than the upper limit of the last partition, the row are rejected (with an error, if the IGNORE keyword is not used).

As a catchall, `MAXVALUE` can be specified as a value for the last partition. Note, however, that in order to append a new partition, it is not possible to use ADD PARTITION; instead, REORGANIZE PARTITION must be used.

Use Cases

A typical use case is when we want to partition a table whose rows refer to a moment or period in time; for example commercial transactions, blog posts, or events of some kind. We can partition the table by year, to keep all recent data in one partition and distribute historical data in big partitions that are stored on slower disks. Or, if our queries always read rows which refer to the same month or week, we can partition the table by month or year week (in this case, historical data and recent data are stored together).

AUTO_INCREMENT values also represent a chronological order. So, these values can be used to store old data in separate partitions. However, partitioning by id is not the best choice if we usually query a table by date.

Examples

Partitioning a log table by year:

```
CREATE TABLE log
(
    id INT UNSIGNED NOT NULL AUTO_INCREMENT,
    dt DATETIME NOT NULL,
    user INT UNSIGNED,
    PRIMARY KEY (id, dt)
)
    ENGINE = InnoDB
PARTITION BY RANGE (YEAR(dt))
(
    PARTITION p0 VALUES LESS THAN (2013),
    PARTITION p1 VALUES LESS THAN (2014),
    PARTITION p2 VALUES LESS THAN (2015),
    PARTITION p3 VALUES LESS THAN (2016)
);
```

Partitioning the table by both year and month:

```
CREATE TABLE log2
(
    id INT UNSIGNED NOT NULL AUTO_INCREMENT,
    ts TIMESTAMP NOT NULL,
    user INT UNSIGNED,
    PRIMARY KEY (id, ts)
)
    ENGINE = InnoDB
PARTITION BY RANGE (UNIX_TIMESTAMP(ts))
(
    PARTITION p0 VALUES LESS THAN (UNIX_TIMESTAMP('2014-08-01 00:00:00')),
    PARTITION p1 VALUES LESS THAN (UNIX_TIMESTAMP('2014-11-01 00:00:00')),
    PARTITION p2 VALUES LESS THAN (UNIX_TIMESTAMP('2015-01-01 00:00:00')),
    PARTITION p3 VALUES LESS THAN (UNIX_TIMESTAMP('2015-02-01 00:00:00'))
);
```

In the last example, the UNIX_TIMESTAMP function is used to accomplish the purpose. Also, the first two partitions cover longer periods of time (probably because the logged activities were less intensive).

In both cases, when our tables become huge and we don't need to store all historical data any more, we can drop the oldest partitions in this way:

```
ALTER TABLE log DROP PARTITION p0;
```

We will still be able to drop a partition that does not contain the oldest data, but all rows stored in it will disappear.

Example of an error when inserting outside a defined partition range:

```
INSERT INTO log(id,dt) VALUES
  (1, '2016-01-01 01:01:01'),
  (2, '2015-01-01 01:01:01');
ERROR 1526 (HY000): Table has no partition for value 2016
```

To avoid the error, use the `IGNORE` keyword:

```
INSERT IGNORE INTO log(id,dt) VALUES
  (1, '2016-01-01 01:01:01'),
  (2, '2015-01-01 01:01:01');

SELECT * FROM log;
+----+---------------------+------+
| id | timestamp           | user |
+----+---------------------+------+
|  2 | 2015-01-01 01:01:01 | NULL |
+----+---------------------+------+
```

An alternative definition with `MAXVALUE` as a catchall:

```
CREATE TABLE log
(
    id INT UNSIGNED NOT NULL AUTO_INCREMENT,
    dt DATETIME NOT NULL,
    user INT UNSIGNED,
    PRIMARY KEY (id, dt)
)
    ENGINE = InnoDB
PARTITION BY RANGE (YEAR(dt))
(
    PARTITION p0 VALUES LESS THAN (2013),
    PARTITION p1 VALUES LESS THAN (2014),
    PARTITION p2 VALUES LESS THAN (2015),
    PARTITION p3 VALUES LESS THAN (2016),
    PARTITION p4 VALUES LESS THAN MAXVALUE
);
```

Partitioning Limitations

The following limitations apply to partitioning in MariaDB:

- Each table can contain a maximum of 8192 partitions.
- Queries are never parallelized, even when they involve multiple partitions.
- A table can only be partitioned if the storage engine supports partitioning.
- All partitions must use the same storage engine. For a workaround, see Using CONNECT - Partitioning and Sharding.
- A partitioned table cannot contain, or be referenced by, foreign keys.
- The query cache is not aware of partitioning and partition pruning. Modifying a partition will invalidate the entries related to the whole table.
- Updates can run more slowly when binlog_format=ROW and a partitioned table is updated than an equivalent update of a non-partitioned table.
- All columns used in the partitioning expression for a partitioned table must be part of every unique key that the table may have.
- In versions prior to MariaDB 11.3.2, it is not possible to create partitions on tables that contain GEOMETRY types.

Partitions Files

A partitioned table is stored in multiple files. By default, these files are stored in the MariaDB (or InnoDB) data directory. It is possible to keep them in different paths by specifying DATA_DIRECTORY and INDEX_DIRECTORY table options. This is useful to store different partitions on different devices.

Note that, if the innodb_file_per_table server system variable is set to 0 at the time of the table creation, all partitions are stored in the system tablespace.

The following files exist for each partitioned tables:

File name	Notes
table_name.frm	Contains the table definition. Non-partitioned tables have this file, too.
table_name.par	Contains the partitions definitions.
table_name#P#partition_name .ext	Normal files created by the storage engine use this pattern for names. The extension depends on the storage engine.

For example, an InnoDB table with 4 partitions will have the following files:

```
orders.frm
orders.par
orders#P#p0.ibd
orders#P#p1.ibd
orders#P#p2.ibd
orders#P#p3.ibd
```

If we convert the table to MyISAM, we will have these files:

```
orders.frm
orders.par
orders#P#p0.MYD
orders#P#p0.MYI
orders#P#p1.MYD
orders#P#p1.MYI
orders#P#p2.MYD
orders#P#p2.MYI
orders#P#p3.MYD
orders#P#p3.MYI
```

Partitions Metadata

The PARTITIONS table in the INFORMATION_SCHEMA database contains information about partitions.

The SHOW TABLE STATUS statement contains a `Create_options` column, that contains the string 'partitioned' for partitioned tables.

The SHOW CREATE TABLE statement returns the CREATE TABLE statement that can be used to re-create a table, including the partitions definition.

Stored Routines

See Stored Procedures.

Master stored procedures in MariaDB Server. This section covers creating, executing, and managing these powerful routines to encapsulate complex logic and improve application performance.

See Stored Functions.

Utilize stored functions in MariaDB Server. This section details creating, using, and managing user-defined functions to extend SQL capabilities and streamline data manipulation.

See Binary Logging of Stored Routines.

When binary logging is enabled, stored routines may require special handling (like SUPER privileges) if they are non-deterministic, to ensure consistent replication.

See Stored Routine Limitations.

Stored routines have specific restrictions, such as prohibiting certain SQL statements (e.g., LOAD DATA) and disallowing result sets in functions.

See DBMS_OUTPUT.

The DBMS_OUTPUT plugin provides Oracle-compatible output buffering functions (like PUT_LINE), allowing stored procedures to send messages to the client.

This page is licensed: CC BY-SA / Gnu FDL

Stored Procedures

See Stored Procedure Overview.

Stored procedures are precompiled collections of SQL statements stored on the server, allowing for encapsulated logic, parameterized execution, and improved application performance.

See CREATE PROCEDURE.

Complete CREATE PROCEDURE guide for MariaDB. Complete reference documentation for implementation, configuration, and usage with comprehensive examples and.

See ALTER PROCEDURE.

The ALTER PROCEDURE statement modifies the characteristics of an existing stored procedure, such as its security context or comment, without changing its logic.

See DROP PROCEDURE.

The DROP PROCEDURE statement permanently removes a stored procedure and its associated privileges from the database.

This page is licensed: CC BY-SA / Gnu FDL

Stored Procedure Overview

A Stored Procedure is a routine invoked with a CALL statement. It may have input parameters, output parameters and parameters that are both input parameters and output parameters.

Creating a Stored Procedure

Here's a skeleton example to see a stored procedure in action:

```
DELIMITER //

CREATE PROCEDURE Reset_animal_count()
 MODIFIES SQL DATA
 UPDATE animal_count SET animals = 0;
//

DELIMITER ;
```

First, the delimiter is changed, since the procedure definition will contain the regular semicolon delimiter. The procedure is named `Reset_animal_count`. `MODIFIES SQL DATA` indicates that the procedure will perform a write action of sorts, and modify data. It's for advisory purposes only. Finally, there's the actual SQL statement - an `UPDATE`.

```
SELECT * FROM animal_count;
+---------+
| animals |
+---------+
|     101 |
+---------+

CALL Reset_animal_count();

SELECT * FROM animal_count;
+---------+
| animals |
+---------+
|       0 |
+---------+
```

A more complex example, with input parameters, from an actual procedure used by banks:

```
CREATE PROCEDURE
  Withdraw                             /* Routine name */
  (parameter_amount DECIMAL(6,2),     /* Parameter list */
  parameter_teller_id INTEGER,
  parameter_customer_id INTEGER)
  MODIFIES SQL DATA                   /* Data access clause */
  BEGIN                         /* Routine body */
    UPDATE Customers
        SET balance = balance - parameter_amount
        WHERE customer_id = parameter_customer_id;
    UPDATE Tellers
        SET cash_on_hand = cash_on_hand + parameter_amount
        WHERE teller_id = parameter_teller_id;
    INSERT INTO Transactions VALUES (
        parameter_customer_id,
        parameter_teller_id,
        parameter_amount);
  END;
```

See CREATE PROCEDURE for full syntax details.

Why Use Stored Procedures?

Security is a key reason. Banks commonly use stored procedures so that applications and users don't have direct access to the tables. Stored procedures are also useful in an environment where multiple languages and clients are all used to perform the same operations.

Stored Procedure Listings and Definitions

To find which stored procedures are defined on the server, use SHOW PROCEDURE STATUS.

```
SHOW PROCEDURE STATUS\G
*************************** 1. row ***************************
                  Db: test
                Name: Reset_animal_count
                Type: PROCEDURE
             Definer: root@localhost
            Modified: 2013-06-03 08:55:03
             Created: 2013-06-03 08:55:03
       Security_type: DEFINER
             Comment:
character_set_client: utf8
collation_connection: utf8_general_ci
  Database Collation: latin1_swedish_ci
```

or query the routines table in the INFORMATION_SCHEMA database directly:

```
SELECT ROUTINE_NAME FROM INFORMATION_SCHEMA.ROUTINES
  WHERE ROUTINE_TYPE='PROCEDURE';
+--------------------+
| ROUTINE_NAME       |
+--------------------+
| Reset_animal_count |
+--------------------+
```

To find out what the stored procedure does, use SHOW CREATE PROCEDURE.

```
SHOW CREATE PROCEDURE Reset_animal_count\G
*************************** 1. row ***************************
           Procedure: Reset_animal_count
            sql_mode:
    Create Procedure: CREATE DEFINER=`root`@`localhost` PROCEDURE `Reset_animal_count`()
    MODIFIES SQL DATA
UPDATE animal_count SET animals = 0
character_set_client: utf8
collation_connection: utf8_general_ci
  Database Collation: latin1_swedish_ci
```

Dropping and Updating a Stored Procedure

To drop a stored procedure, use the DROP PROCEDURE statement.

```
DROP PROCEDURE Reset_animal_count;
```

To change the characteristics of a stored procedure, use ALTER PROCEDURE. However, you cannot change the parameters or body of a stored procedure using this statement; to make such changes, you must drop and re-create the procedure using CREATE OR REPLACE PROCEDURE (which retains existing privileges), or DROP PROCEDURE followed by CREATE PROCEDURE.

Permissions in Stored Procedures

See the article Stored Routine Privileges.

This page is licensed: CC BY-SA / Gnu FDL

CREATE PROCEDURE

Syntax

CURRENT

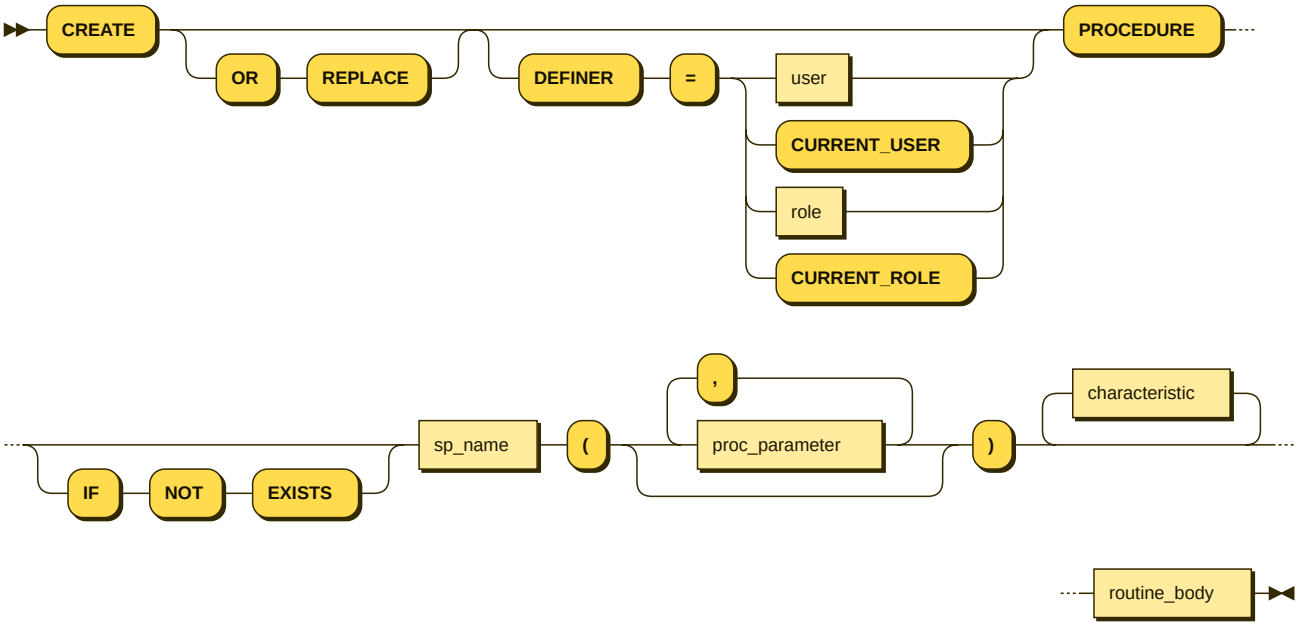
```
CREATE
    [OR REPLACE]
    [DEFINER = { user | CURRENT_USER | role | CURRENT_ROLE }]
    PROCEDURE [IF NOT EXISTS] sp_name ([proc_parameter[,...]])
    [characteristic ...] routine_body

proc_parameter:
    [ OUT | INOUT | IN OUT] param_name type |
    [ IN ] param_name type [DEFAULT value or expression]

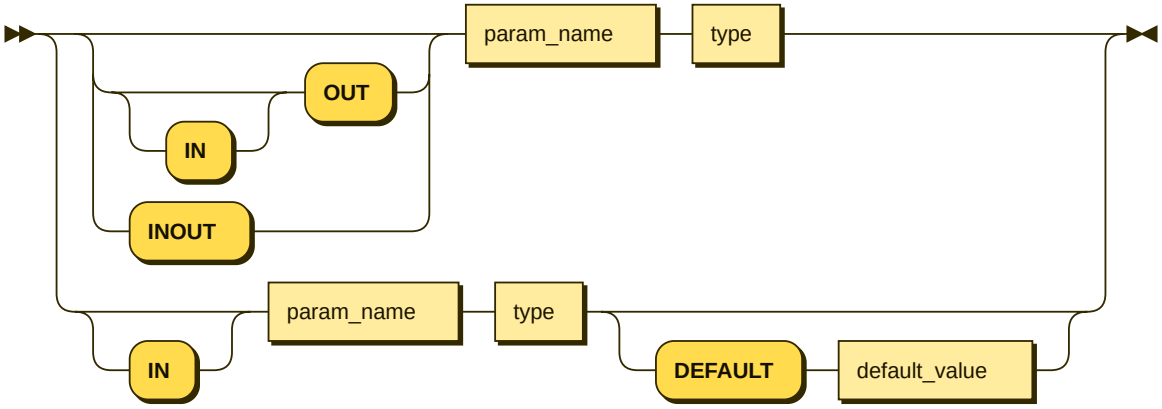
type:
    Any valid MariaDB data type

characteristic:
    LANGUAGE SQL
  | [NOT] DETERMINISTIC
  | { CONTAINS SQL | NO SQL | READS SQL DATA | MODIFIES SQL DATA }
  | SQL SECURITY { DEFINER | INVOKER }
  | COMMENT 'string'

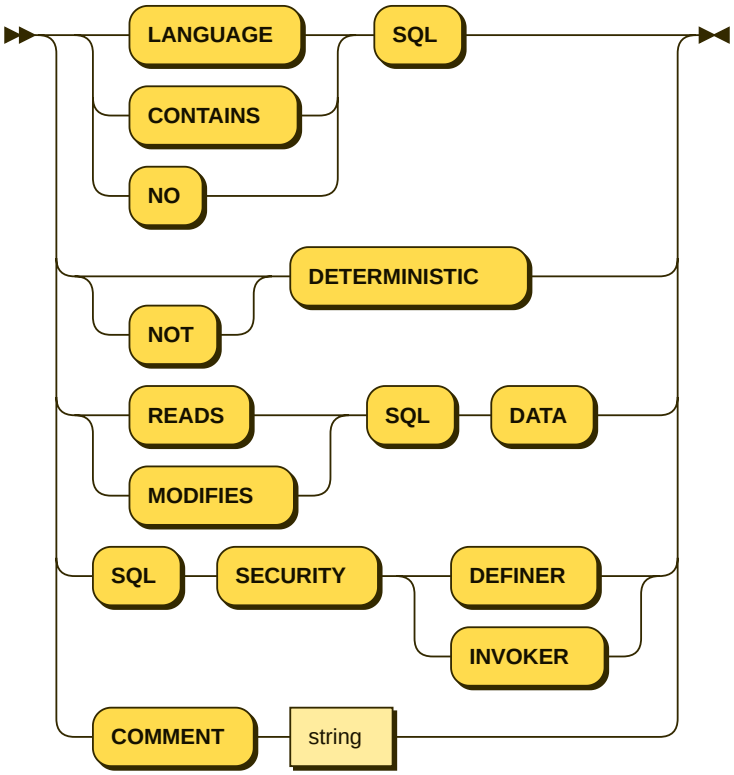
routine_body:
    Valid SQL procedure statement
```



Railroad diagram of CREATE PROCEDURE — equivalent to the BNF above



Railroad diagram of proc_parameter



Railroad diagram of characteristic

The `IN OUT` parameter works only in Oracle mode.

< 11.8

```
CREATE
    [OR REPLACE]
    [DEFINER = { user | CURRENT_USER | role | CURRENT_ROLE }]
    PROCEDURE [IF NOT EXISTS] sp_name ([proc_parameter[,...]])
    [characteristic ...] routine_body

proc_parameter:
    [ IN | OUT | INOUT ] param_name type

type:
    Any valid MariaDB data type

characteristic:
    LANGUAGE SQL
  | [NOT] DETERMINISTIC
  | { CONTAINS SQL | NO SQL | READS SQL DATA | MODIFIES SQL DATA }
  | SQL SECURITY { DEFINER | INVOKER }
  | COMMENT 'string'

routine_body:
    Valid SQL procedure statement
```

Description

Creates a stored procedure. By default, a routine is associated with the default database. To associate the routine explicitly with a given database, specify the name as `db_name.sp_name` when you create it.

When the routine is invoked, an implicit `USE``db_name` is performed (and undone when the routine terminates). The causes the routine to have the given default database while it executes. `USE` statements within stored routines are disallowed.

When a stored procedure has been created, you invoke it by using the `CALL` statement (see CALL).

To execute the `CREATE PROCEDURE` statement, it is necessary to have the `CREATE ROUTINE` privilege. By default, MariaDB automatically grants the `ALTER ROUTINE` and `EXECUTE` privileges to the routine creator. See also Stored Routine Privileges.

The `DEFINER` and `SQL SECURITY` clauses specify the security context to be used when checking access privileges at routine execution time, as described here. Requires the SET USER privilege.

If the routine name is the same as the name of a built-in SQL function, you must use a space between the name and the following parenthesis when defining the routine, or a syntax error occurs. This is also true when you invoke the routine later. For this reason, we suggest that it is better to avoid reusing the names of existing SQL functions for your own stored routines.

The `IGNORE_SPACE` SQL mode applies to built-in functions, not to stored routines. It is always allowable to have spaces after a routine name, regardless of whether `IGNORE_SPACE` is enabled.

The parameter list enclosed within parentheses must always be present. If there are no parameters, an empty parameter list of `()` should be used. Parameter names are not case sensitive.

For valid identifiers to use as procedure names, see Identifier Names.

Things to be Aware of With CREATE OR REPLACE

- One can't use `OR REPLACE` together with `IF EXISTS`.

CREATE PROCEDURE IF NOT EXISTS

If the `IF NOT EXISTS` clause is used, then the procedure will only be created if a procedure with the same name does not already exist. If the procedure already exists, then a warning are triggered by default.

IN/OUT/INOUT/IN OUT

Each parameter is an `IN` parameter by default. To specify otherwise for a parameter, use the keyword `OUT` or `INOUT` before the parameter name.

An `IN` parameter passes a value into a procedure. The procedure might modify the value, but the modification is not visible to the caller when the procedure returns. An `OUT` parameter passes a value from the procedure back to the caller. Its initial value is `NULL` within the procedure, and its value is visible to the caller when the procedure returns. An `INOUT` parameter is initialized by the caller, can be modified by the procedure, and any change made by the procedure is visible to the caller when the procedure returns.

For each `OUT` or `INOUT` parameter, pass a user-defined variable in the `CALL` statement that invokes the procedure so that you can obtain its value when the procedure returns. If you are calling the procedure from within another stored procedure or function, you can also pass a routine parameter or local routine variable as an `IN` or `INOUT` parameter.

DEFAULT value or expression

As of MariaDB 11.8, each parameter can be defined as having a default value or expression. This can be useful if needing to add extra parameters to a procedure which is already in use.

DETERMINISTIC/NOT DETERMINISTIC

`DETERMINISTIC` and `NOT DETERMINISTIC` apply only to functions. Specifying `DETERMINISTC` or `NON-DETERMINISTIC` in procedures has no effect. The default value is `NOT DETERMINISTIC`. Functions are `DETERMINISTIC` when they always return the same value for the same input. For example, a truncate or substring function. Any function involving data, therefore, is always `NOT DETERMINISTIC`.

CONTAINS SQL/NO SQL/READS SQL DATA/MODIFIES SQL DATA

`CONTAINS SQL`, `NO SQL`, `READS SQL DATA`, and `MODIFIES SQL DATA` are informative clauses that tell the server what the function does. MariaDB does not check in any way whether the specified clause is correct. If none of these clauses are specified, `CONTAINS SQL` is used by default.

`MODIFIES SQL DATA` means that the function contains statements that may modify data stored in databases. This happens if the function contains statements like DELETE, UPDATE, INSERT, REPLACE or DDL.

`READS SQL DATA` means that the function reads data stored in databases but does not modify any data. This happens if SELECT statements are used, but there no write operations are executed.

`CONTAINS SQL` means that the function contains at least one SQL statement, but it does not read or write any data stored in a database. Examples include SET or DO.

`NO SQL` means nothing, because MariaDB does not currently support any language other than SQL.

The routine_body consists of a valid SQL procedure statement. This can be a simple statement such as SELECT or INSERT, or it can be a compound statement written using BEGIN and END. Compound statements can contain declarations, loops, and other control structure statements. See Programmatic and Compound Statements for syntax details.

MariaDB allows routines to contain DDL statements, such as `CREATE` and `DROP`. MariaDB also allows stored procedures (but not stored functions) to contain SQL transaction statements such as `COMMIT`.

For additional information about statements that are not allowed in stored routines, see Stored Routine Limitations.

Invoking stored procedure from within programs

For information about invoking stored procedures from within programs written in a language that has a MariaDB/MySQL interface, see CALL.

OR REPLACE

If the optional `OR REPLACE` clause is used, it acts as a shortcut for the following statements, with the exception that any existing privileges for the procedure are not dropped:

```
DROP PROCEDURE IF EXISTS name;
CREATE PROCEDURE name ...;
```

sql_mode

MariaDB stores the sql_mode system variable setting that is in effect at the time a routine is created and always executes the routine with this setting in force, regardless of the server SQL mode in effect when the routine is invoked.

Character Sets and Collations

Procedure parameters can be declared with any character set/collation. If the character set and collation are not specifically set, the database defaults at the time of creation are used. If the database defaults change at a later stage, the stored procedure character set/collation will not be changed at the same time; the stored procedure needs to be dropped and recreated to ensure the same character set/collation as the database is used.

Oracle Mode

A subset of Oracle's PL/SQL language is supported in addition to the traditional SQL/PSM-based MariaDB syntax. See Oracle mode for details on changes when running Oracle mode.

Examples

The following example shows a simple stored procedure that uses an `OUT` parameter. It uses the `DELIMITER` command to set a new delimiter for the duration of the process — see Delimiters in the mariadb client.

```
DELIMITER //

CREATE PROCEDURE simpleproc (OUT param1 INT)
 BEGIN
  SELECT COUNT(*) INTO param1 FROM t;
 END;
//

DELIMITER ;

CALL simpleproc(@a);

SELECT @a;
+------+
| @a   |
+------+
|    1 |
+------+
```

Character set and collation:

```
DELIMITER //

CREATE PROCEDURE simpleproc2 (
  OUT param1 CHAR(10) CHARACTER SET 'utf8' COLLATE 'utf8_bin'
)
 BEGIN
  SELECT CONCAT('a'),f1 INTO param1 FROM t;
 END;
//

DELIMITER ;
```

`CREATE OR REPLACE`:

Re-creating an existing procedure without `OR REPLACE` fails, while `CREATE OR REPLACE` replaces the existing definition:

```
DELIMITER //

CREATE PROCEDURE simpleproc2 (
  OUT param1 CHAR(10) CHARACTER SET 'utf8' COLLATE 'utf8_bin'
)
 BEGIN
  SELECT CONCAT('a'),f1 INTO param1 FROM t;
 END;
//
ERROR 1304 (42000): PROCEDURE simpleproc2 already exists

CREATE OR REPLACE PROCEDURE simpleproc2 (
  OUT param1 CHAR(10) CHARACTER SET 'utf8' COLLATE 'utf8_bin'
)
 BEGIN
  SELECT CONCAT('a'),f1 INTO param1 FROM t;
 END;
//
Query OK, 0 rows affected (0.03 sec)

DELIMITER ;
```

ALTER PROCEDURE

Syntax

```
ALTER PROCEDURE proc_name [characteristic ...]

characteristic:
    { CONTAINS SQL | NO SQL | READS SQL DATA | MODIFIES SQL DATA }
  | SQL SECURITY { DEFINER | INVOKER }
  | COMMENT 'string'
```

Description

This statement can be used to change the characteristics of a stored procedure. More than one change may be specified in an `ALTER PROCEDURE` statement. However, you cannot change the parameters or body of a stored procedure using this statement. To make such changes, you must drop and re-create the procedure using CREATE OR REPLACE PROCEDURE.

You must have the `ALTER ROUTINE` privilege for the procedure. By default, that privilege is granted automatically to the procedure creator. See Stored Routine Privileges.

Example

```
ALTER PROCEDURE simpleproc SQL SECURITY INVOKER;
```

- Stored Procedure Overview
- CREATE PROCEDURE
- SHOW CREATE PROCEDURE
- DROP PROCEDURE
- SHOW CREATE PROCEDURE
- SHOW PROCEDURE STATUS
- Stored Routine Privileges
- Information Schema ROUTINES Table

This page is licensed: GPLv2, originally from fill_help_tables.sql

DROP PROCEDURE

Syntax

```
DROP PROCEDURE [IF EXISTS] sp_name
```

Description

This statement is used to drop a stored procedure. That is, the specified routine is removed from the server along with all privileges specific to the procedure. You must have the `ALTER ROUTINE` privilege for the routine. If the automatic_sp_privileges server system variable is set, that privilege and `EXECUTE` are granted automatically to the routine creator - see Stored Routine Privileges.

The `IF EXISTS` clause is a MySQL/MariaDB extension. It prevents an error from occurring if the procedure or function does not exist. A `NOTE` is produced that can be viewed with SHOW WARNINGS.

While this statement takes effect immediately, threads which are executing a procedure can continue execution.

Examples

```
DROP PROCEDURE simpleproc;
```

IF EXISTS:

```
DROP PROCEDURE simpleproc;
ERROR 1305 (42000): PROCEDURE test.simpleproc does not exist

DROP PROCEDURE IF EXISTS simpleproc;
Query OK, 0 rows affected, 1 warning (0.00 sec)

SHOW WARNINGS;
+-------+------+-----------------------------------------+
| Level | Code | Message                                 |
+-------+------+-----------------------------------------+
| Note  | 1305 | PROCEDURE test.simpleproc does not exist |
+-------+------+-----------------------------------------+
```

Stored Functions

See Stored Function Overview.

A Stored Function is a set of SQL statements that can be called by name, accepts parameters, and returns a single value, enhancing SQL with custom logic.

See Stored Aggregate Functions.

Stored Aggregate Functions allow users to create custom aggregate functions that process a sequence of rows and return a single summary result.

See Stored Routine Privileges.

This page explains the privileges required to create, alter, execute, and drop stored routines, including the automatic grants for creators.

See DROP FUNCTION.

The DROP FUNCTION statement removes a stored function from the database, deleting its definition and associated privileges.

See Stored Function Limitations.

This page details the restrictions on stored functions, such as the inability to return result sets or use transaction control statements.

This page is licensed: CC BY-SA / Gnu FDL

Stored Function Overview

A Stored Function is a defined function that is called from within an SQL statement like a regular function and returns a single value.

Creating Stored Functions

Here's a skeleton example to see a stored function in action:

```
DELIMITER //

CREATE FUNCTION FortyTwo() RETURNS TINYINT DETERMINISTIC
BEGIN
 DECLARE x TINYINT;
 SET x = 42;
 RETURN x;
END

//

DELIMITER ;
```

First, the delimiter is changed, since the function definition will contain the regular semicolon delimiter. See Delimiters in the mariadb client for more. Then the function is named `FortyTwo` and defined to return a `tinyin`. The `DETERMINISTIC` keyword is not necessary in all cases (although if binary logging is on, leaving it out will throw an error), and is to help the query optimizer choose a query plan. A deterministic function is one that, given the same arguments, will always return the same result.

Next, the function body is placed between BEGIN and END statements. It declares a tinyint, `X`, which is simply set to 42, and this is the result returned.

```
SELECT FortyTwo();
+------------+
| FortyTwo() |
+------------+
|         42 |
+------------+
```

Of course, a function that doesn't take any arguments is of little use. Here's a more complex example:

```
DELIMITER //
CREATE FUNCTION VatCents(price DECIMAL(10,2)) RETURNS INT DETERMINISTIC
BEGIN
 DECLARE x INT;
 SET x = price * 114;
 RETURN x;
END //
Query OK, 0 rows affected (0.04 sec)
DELIMITER ;
```

This function takes an argument, `price` which is defined as a DECIMAL, and returns an INT.

Take a look at the CREATE FUNCTION page for more details.

It is also possible to create stored aggregate functions.

Stored Function Listings and Definitions

To find which stored functions are running on the server, use SHOW FUNCTION STATUS:

```
SHOW FUNCTION STATUS\G
*************************** 1. row ***************************
                  Db: test
                Name: VatCents
                Type: FUNCTION
             Definer: root@localhost
            Modified: 2013-06-01 12:40:31
             Created: 2013-06-01 12:40:31
       Security_type: DEFINER
             Comment:
character_set_client: utf8
collation_connection: utf8_general_ci
  Database Collation: latin1_swedish_ci
1 row in set (0.00 sec)
```

Alternatively, query the routines table in the `INFORMATION_SCHEMA` database directly:

```
SELECT ROUTINE_NAME FROM INFORMATION_SCHEMA.ROUTINES WHERE
  ROUTINE_TYPE='FUNCTION';
+--------------+
| ROUTINE_NAME |
+--------------+
| VatCents     |
+--------------+
```

To find out what the stored function does, use SHOW CREATE FUNCTION:

```
SHOW CREATE FUNCTION VatCents\G
*************************** 1. row ***************************
            Function: VatCents
            sql_mode:
     Create Function: CREATE DEFINER=`root`@`localhost` FUNCTION `VatCents`(price DECIMAL(10,2)) RETURNS
int(11)
    DETERMINISTIC
BEGIN
 DECLARE x INT;
 SET x = price * 114;
 RETURN x;
END
character_set_client: utf8
collation_connection: utf8_general_ci
  Database Collation: latin1_swedish_ci
```

Dropping and Updating Stored Functions

To drop a stored function, use the DROP FUNCTION statement.

```
DROP FUNCTION FortyTwo;
```

To change the characteristics of a stored function, use ALTER FUNCTION. Note that you cannot change the parameters or body of a stored function using this statement; to make such changes, you must drop and re-create the function using `DROP FUNCTION` and `CREATE FUNCTION`.

Permissions in Stored Functions

See the article Stored Routine Privileges.

Stored Aggregate Functions

Aggregate functions are functions that are computed over a sequence of rows and return one result for the sequence of rows.

Creating a custom aggregate function is done using the CREATE FUNCTION statement with two main differences:

- The addition of the AGGREGATE keyword, so `CREATE AGGREGATE FUNCTION`
- The `FETCH GROUP NEXT ROW` instruction inside the loop
- Oracle PL/SQL compatibility using SQL/PL is provided

Standard Syntax

```
CREATE AGGREGATE FUNCTION function_name (parameters) RETURNS return_type
BEGIN
      ALL types of declarations
      DECLARE CONTINUE HANDLER FOR NOT FOUND RETURN return_val;
      LOOP
           FETCH GROUP NEXT ROW; // fetches next row FROM TABLE
           other instructions
      END LOOP;
END
```

Stored aggregate functions were a 2016 Google Summer of Code project by Varun Gupta.

Using SQL/PL

```
SET sql_mode=Oracle;
DELIMITER //

CREATE AGGREGATE FUNCTION function_name (parameters) RETURN return_type
   declarations
BEGIN
   LOOP
      FETCH GROUP NEXT ROW; -- fetches next row from table
      -- other instructions

   END LOOP;
EXCEPTION
   WHEN NO_DATA_FOUND THEN
      RETURN return_val;
END //

DELIMITER ;
```

Examples

First a simplified example:

```
CREATE TABLE marks(stud_id INT, grade_count INT);

INSERT INTO marks VALUES (1,6), (2,4), (3,7), (4,5), (5,8);

SELECT * FROM marks;
+---------+-------------+
| stud_id | grade_count |
+---------+-------------+
|       1 |           6 |
|       2 |           4 |
|       3 |           7 |
|       4 |           5 |
|       5 |           8 |
+---------+-------------+

DELIMITER //
CREATE AGGREGATE FUNCTION IF NOT EXISTS aggregate_count(x INT) RETURNS INT
BEGIN
 DECLARE count_students INT DEFAULT 0;
 DECLARE CONTINUE HANDLER FOR NOT FOUND
 RETURN count_students;
      LOOP
          FETCH GROUP NEXT ROW;
          IF x  THEN
            SET count_students = count_students+1;
          END IF;
      END LOOP;
END //
DELIMITER ;
```

A non-trivial example that cannot easily be rewritten using existing functions:

```
DELIMITER //
CREATE AGGREGATE FUNCTION medi_int(x INT) RETURNS DOUBLE
BEGIN
  DECLARE CONTINUE HANDLER FOR NOT FOUND
    BEGIN
      DECLARE res DOUBLE;
      DECLARE cnt INT DEFAULT (SELECT COUNT(*) FROM tt);
      DECLARE lim INT DEFAULT (cnt-1) DIV 2;
      IF cnt % 2 = 0 THEN
        SET res = (SELECT AVG(a) FROM (SELECT a FROM tt ORDER BY a LIMIT lim,2) ttt);
      ELSE
        SET res = (SELECT a FROM tt ORDER BY a LIMIT lim,1);
      END IF;
      DROP TEMPORARY TABLE tt;
      RETURN res;
    END;
  CREATE TEMPORARY TABLE tt (a INT);
  LOOP
    FETCH GROUP NEXT ROW;
    INSERT INTO tt VALUES (x);
  END LOOP;
END //
DELIMITER ;
```

SQL/PL Example

This uses the same marks table as created above.

```
SET sql_mode=Oracle;
DELIMITER //

CREATE AGGREGATE FUNCTION aggregate_count(x INT) RETURN INT AS count_students INT DEFAULT 0;
BEGIN
   LOOP
      FETCH GROUP NEXT ROW;
      IF x  THEN
        SET count_students := count_students+1;
      END IF;
   END LOOP;
EXCEPTION
   WHEN NO_DATA_FOUND THEN
      RETURN count_students;
END aggregate_count //
DELIMITER ;

SELECT aggregate_count(stud_id) FROM marks;
```

Stored Routine Privileges

It's important to give careful thought to the privileges associated with stored functions and stored procedures. The following is an explanation of how they work.

Creating Stored Routines

- To create a stored routine, the CREATE ROUTINE privilege is needed. The SUPER privilege is required if a `DEFINER` is declared that's not the creator's account (see DEFINER clause below). The `SUPER` privilege is also required if statement-based binary logging is used. See Binary Logging of Stored Routines for more details.

Altering Stored Routines

- To make changes to, or drop, a stored routine, the ALTER ROUTINE privilege is needed. The creator of a routine is temporarily granted this privilege if they attempt to change or drop a routine they created, unless the automatic_sp_privileges variable is set to `0` (it defaults to 1).
- The `SUPER` privilege is also required if statement-based binary logging is used. See Binary Logging of Stored Routines for more details.

Running Stored Routines

- To run a stored routine, the EXECUTE privilege is needed. This is also temporarily granted to the creator if they attempt to run their routine unless the automatic_sp_privileges variable is set to `0`.
- The SQL SECURITY clause (by default `DEFINER`) specifies what privileges are used when a routine is called. If `SQL SECURITY` is `INVOKER`, the function body are evaluated using the privileges of the user calling the function. If `SQL SECURITY` is `DEFINER`, the function body is always evaluated using the privileges of the definer account. `DEFINER` is the default. Thus, by default, users who can access the database associated with the stored routine can also run the routine, and potentially perform operations they wouldn't normally have permissions for.
- The creator of a routine is the account that ran the CREATE FUNCTION or CREATE PROCEDURE statement, regardless of whether a `DEFINER` is provided. The definer is by default the creator unless otherwise specified.
- The server automatically changes the privileges in the mysql.proc table as required, but will not look out for manual changes.

DEFINER Clause

If left out, the `DEFINER` is treated as the account that created the stored routine or view. If the account creating the routine has the `SUPER` privilege, another account can be specified as the `DEFINER`.

SQL SECURITY Clause

This clause specifies the context the stored routine or view will run as. It can take two values - `DEFINER` or `INVOKER`. `DEFINER` is the account specified as the `DEFINER` when the stored routine or view was created (see the section above). `INVOKER` is the account invoking the routine or view.

As an example, let's assume a routine, created by a superuser who's specified as the `DEFINER`, deletes all records from a table. If `SQL SECURITY=DEFINER`, anyone running the routine, regardless of whether they have delete privileges, are able to delete the records. If `SQL SECURITY = INVOKER`, the routine will only delete the records if the account invoking the routine has permission to do so.

`INVOKER` is usually less risky, as a user cannot perform any operations they're normally unable to. However, it's not uncommon for accounts to have relatively limited permissions, but be specifically granted access to routines, which are then invoked in the `DEFINER` context.

Dropping Stored Routines

All privileges that are specific to a stored routine are dropped when a DROP FUNCTION or DROP ROUTINE is run. However, if a CREATE OR REPLACE FUNCTION or CREATE OR REPLACE PROCEDURE is used to drop and replace and the routine, any privileges specific to that routine will not be dropped.

See Also

- Changing the DEFINER of MySQL stored routines etc. - maria.com post on what to do after you've dropped a user, and now want to change the DEFINER on all database objects that currently have it set to this dropped user.

This page is licensed: CC BY-SA / Gnu FDL

DROP FUNCTION

Syntax

```
DROP FUNCTION [IF EXISTS] f_name
```

Description

The `DROP FUNCTION` statement is used to drop a stored function or a user-defined function (UDF). That is, the specified routine is removed from the server, along with all privileges specific to the function. You must have the `ALTER ROUTINE` privilege for the routine in order to drop it. If the automatic_sp_privileges server system variable is set, both the `ALTER ROUTINE` and `EXECUTE` privileges are granted automatically to the routine creator - see Stored Routine Privileges.

IF EXISTS

The `IF EXISTS` clause is a MySQL/MariaDB extension. It prevents an error from occurring if the function does not exist. A `NOTE` is produced that can be viewed with SHOW WARNINGS.

For dropping a user-defined functions (UDF), see DROP FUNCTION UDF.

Examples

```
DROP FUNCTION hello;
Query OK, 0 rows affected (0.042 sec)

DROP FUNCTION hello;
ERROR 1305 (42000): FUNCTION test.hello does not exist

DROP FUNCTION IF EXISTS hello;
Query OK, 0 rows affected, 1 warning (0.000 sec)

SHOW WARNINGS;
+-------+------+-----------------------------------+
| Level | Code | Message                           |
+-------+------+-----------------------------------+
| Note  | 1305 | FUNCTION test.hello does not exist |
+-------+------+-----------------------------------+
```

Stored Function Limitations

The following restrictions apply to stored functions.

- All of the restrictions listed in Stored Routine Limitations.
- Any statements that return a result set are not permitted. For example, a regular SELECTs is not permitted, but a SELECT INTO is. A cursor and FETCH statement is permitted.
- FLUSH statements are not permitted.
- Statements that perform explicit or implicit commits or rollbacks are not permitted.
- Cannot be used recursively.
- Cannot make changes to a table that is already in use (reading or writing) by the statement invoking the stored function.
- Cannot refer to a temporary table multiple times under different aliases, even in different statements.
- ROLLBACK TO SAVEPOINT and RELEASE SAVEPOINT statement which are in a stored function cannot refer to a savepoint which has been defined out of the current function.
- Prepared statements (PREPARE, EXECUTE, DEALLOCATE PREPARE) cannot be used, and therefore nor can statements be constructed as strings and then executed.

This page is licensed: CC BY-SA / Gnu FDL

Binary Logging of Stored Routines

Binary logging can be row-based, statement-based, or a mix of the two. See Binary Log Formats for more details on the formats. If logging is statement-based, it is possible that a statement will have different effects on the master and on the slave.

Stored routines are particularly prone to this, for two main reasons:

- stored routines can be non-deterministic, in other words non-repeatable, and therefore have different results each time they are run.
- the slave thread executing the stored routine on the slave holds full privileges, while this may not be the case when the routine was run on the master.

The problems with replication will only occur with statement-based logging. If row-based logging is used, since changes are made to rows based on the master's rows, there is no possibility of the slave and master getting out of sync.

By default, with row-based replication, triggers run on the master, and the effects of their executions are replicated to the slaves. However, it is possible to run triggers on the slaves. See Running triggers on the slave for Row-based events.

How MariaDB Handles Statement-Based Binary Logging of Routines

If the following criteria are met, then there are some limitations on whether stored routines can be created:

- The binary log is enabled, and the binlog_format system variable is set to `STATEMENT`. See Binary Log Formats for more information.

- The log_bin_trust_function_creators is set to `OFF`, which is the default value.

If the above criteria are met, then the following limitations apply:

- When a stored function is created, it must be declared as either `DETERMINISTIC`, `NO SQL` or `READS SQL DATA`, or else an error will occur. MariaDB cannot check whether a function is deterministic, and relies on the correct definition being used.
- To create or modify a stored function, a user requires the `SUPER` privilege as well as the regular privileges. See Stored Routine Privileges for these details.
- Triggers work in the same way, except that they are always assumed to be deterministic for logging purposes, even if this is obviously not the case, such as when they use the UUID function.
- Triggers can also update data. The slave uses the DEFINER attribute to determine which user is taken to have created the trigger.
- Note that the above limitations do no apply to stored procedures or to events.

Examples

A deterministic function:

```
DELIMITER //

CREATE FUNCTION trust_me(x INT)
RETURNS INT
DETERMINISTIC
READS SQL DATA
BEGIN
   RETURN (x);
END //

DELIMITER ;
```

A non-deterministic function, since it uses the UUID_SHORT function:

```
DELIMITER //

CREATE FUNCTION dont_trust_me()
RETURNS INT
BEGIN
   RETURN UUID_SHORT();
END //

DELIMITER ;
```

This page is licensed: CC BY-SA / Gnu FDL

Stored Routine Limitations

The following SQL statements are not permitted inside any stored routines (stored functions, stored procedures, events or triggers).

- ALTER VIEW; you can use CREATE OR REPLACE VIEW instead.
- LOAD DATA and LOAD TABLE.
- CHANGE MASTER TO
- INSERT DELAYED is permitted, but the statement is handled as a regular INSERT.
- LOCK TABLES and UNLOCK TABLES.
- References to local variables within prepared statements inside a stored routine (use user-defined variables instead).

- BEGIN (WORK) is treated as the beginning of a BEGIN END block, not a transaction, so START TRANSACTION needs to be used instead.
- The number of permitted recursive calls is limited to max_sp_recursion_depth. If this variable is 0 (default), recursivity is disabled. The limit does not apply to stored functions.
- Most statements that are not permitted in prepared statements are not permitted in stored programs. See Prepare Statement:Permitted statements for a list of statements that can be used. SIGNAL, RESIGNAL and GET DIAGNOSTICS are exceptions, and may be used in stored routines.

There are also further limitations specific to the kind of stored routine.

Note that, if a stored program calls another stored program, the latter will inherit the caller's limitations. So, for example, if a stored procedure is called by a stored function, that stored procedure will not be able to produce a result set, because stored functions can't do this.

DBMS_OUTPUT

> **Note:**
>
> This feature is available from MariaDB Enterprise Server 11.8.

Overview

Oracle documentation describing `DBMS_OUTPUT` can be found here:
https://docs.oracle.com/en/database/oracle/oracle-database/21/arpls/DBMS_OUTPUT.html

The main idea of `DBMS_OUTPUT` is:

- Messages submitted by `DBMS_OUTPUT.PUT_LINE()` are not sent to the client until the sending subprogram (or trigger) completes. There is no a way to flush output during the execution of a procedure.
- Therefore, lines are collected into a server side buffer, which, at the end of the current user statement, can be fetched to the client side using another SQL statement. Then, they can be read using a regular MariaDB Connector-C API. No changes in the client-protocol are needed.
- Oracle's SQLPlus uses the procedure `DBMS_PACKAGE.GET_LINES()` to fetch the output to the client side as an array of strings.
- For JDBC, using `GET_LINES()` is preferable, because it's more efficient than individual `GET_LINE()` calls.

Package Routines

Package Overview

MariaDB implements all routines supported by Oracle, except `GET_LINES()`:

- Procedure `ENABLE()` - enable the routines.
- Procedure `DISABLE()` - disable the routines. If the package is disabled, all calls to subprograms, such as `PUT()` and `PUT_LINE()`, are ignored (or exit immediately without doing anything).
- Procedure `PUT_LINE()` - submit a line into the internal buffer.
- Procedure `PUT()` - submit a partial line into the buffer.

- Procedure `NEW_LINE()` - terminate a line submitted by `PUT()`.
- Procedure `GET_LINE()` - read one line (the earliest) from the buffer. When a line is read by `GET_LINE()`, it's automatically removed from the buffer.
- Procedure `GET_LINES()` - read all lines (as an array of strings) from the buffer - this procedure isn't implemented.

The package starts in disabled mode, so an explicit enabling is needed:

```
CALL DBMS_OUTPUT.ENABLE;
```

Details

If a call for `GET_LINE` or `GET_LINES` did not retrieve all lines, then a subsequent call for `PUT`, `PUT_LINE`, or `NEW_LINE` discards the remaining lines (to avoid confusing with the next message). This script demonstrates the principle:

```
DROP TABLE t1;
CREATE TABLE t1 (line VARCHAR2(400), status INTEGER);
DECLARE
  line   VARCHAR2(400);
  status INTEGER;
BEGIN
  DBMS_OUTPUT.PUT_LINE('line1');
  DBMS_OUTPUT.PUT_LINE('line2');
  DBMS_OUTPUT.GET_LINE(line, status);
  INSERT INTO t1 VALUES (line, status);
  DBMS_OUTPUT.PUT_LINE('line3'); -- This clears the buffer (removes line2) before putting line3
  LOOP
    DBMS_OUTPUT.GET_LINE(line, status);
    INSERT INTO t1 VALUES (line, status);
    EXIT WHEN status <> 0;
  END LOOP;
END;
/
SELECT * FROM t1;
```

LINE	STATUS
line1	0
line3	0
-	1

Data Type for the Buffer

Oracle uses this data type as a storage for the buffer:

```
TYPE CHARARR IS TABLE OF VARCHAR2(32767) INDEX BY BINARY_INTEGER;
```

Like Oracle, MariaDB uses an associative array as a storage for the buffer.

Data Type Used for GET_LINES()

> **Warning:**
>
> This functionality is not implemented.

In Oracle, the function `GET_LINES()` returns an array of strings of this data type:

```
TYPE DBMSOUTPUT_LINESARRAY IS VARRAY(2147483647) OF VARCHAR2(32767);
```

MariaDB does not have array data types in the C and C++ connectors, so they can't take advantage of `GET_LINES()` in a client program.

Fetching all Lines in a PL/SQL Program

Fetching all lines in a PL/SQL program is implemented using a loop of `sys.DBMS_OUTPUT.GET_LINE()` calls:

```
SET sql_mode=ORACLE;
DELIMITER /
DECLARE
  all_lines MEDIUMTEXT CHARACTER SET utf8mb4 :='';
  line MEDIUMTEXT CHARACTER SET utf8mb4;
  status INT;
BEGIN
  sys.DBMS_OUTPUT.PUT_LINE('line1');
  sys.DBMS_OUTPUT.PUT_LINE('line2');
  sys.DBMS_OUTPUT.PUT_LINE('line3');
  LOOP
    sys.DBMS_OUTPUT.GET_LINE(line, status);
    EXIT WHEN status > 0;
    all_lines:= all_lines || line || '\n';
  END LOOP;
  SELECT all_lines;
END;
/
DELIMITER ;
```

Fetching all Lines on the Client Side

Fetching all lines on the client side (for instance, in a C program using Connector/C) is done by using a loop of `sys.DBMS_OUTPUT.GET_LINE()` queries.

Limits

Oracle has the following limits:

- The maximum individual line length (sent to `DBMS_OUTPUT`) is 32767 bytes.
- The default buffer size is 20000 bytes. The minimum size is 2000 bytes. The maximum is unlimited.

MariaDB also implements some limits, either using the total size of all rows or using the row count.

Installation

Like other bootstrap scripts, the script creating `DBMS_OUTPUT`:

- Is put into a new separate `/scripts/dbms_ouput.sql` file in the source directory;
- Is installed into `/share/dbms_ouput.sql` of the installation directory.

Storage Engines Overview

Overview

MariaDB features pluggable storage engines to allow per-table workload optimization.

A storage engine is a type of plugin for MariaDB:

- Different storage engines may be optimized for different workloads, such as transactional workloads, analytical workloads, or high throughput workloads.

- Different storage engines may be designed for different use cases, such as federated table access, table sharding, and table archiving in the cloud.
- Different tables on the same server may use different storage engines.

Engine	Target	Optimization	Availability
Aria	Read-Heavy	Reads	ES 10.5+
ColumnStore	Analytics, HTAP	Big Data, Analytical	ES 10.5+
InnoDB	General Purpose	Mixed Read/Write	ES 10.5+
Memory	Cache, Temp	Temporary Data	ES 10.5+
MyISAM	Reads	Reads	ES 10.5+
MyRocks	Write-Heavy	I/O Reduction, SSD	ES 10.5+
S3	Cloud	Read-Only	ES 10.5+
Spider	Federation	Sharding, Interlink	ES 10.5+

Examples

Identify the Default Storage Engine

Identify the server's global default storage engine by using SHOW GLOBAL VARIABLES to query the default_storage_engine system variable:

```
SHOW GLOBAL VARIABLES LIKE 'default_storage_engine';
```

```
+------------------------+--------+
| Variable_name          | Value  |
+------------------------+--------+
| default_storage_engine | InnoDB |
+------------------------+--------+
```

Identify the session's default storage engine by using SHOW SESSION VARIABLES:

```
SHOW SESSION VARIABLES LIKE 'default_storage_engine';
```

```
+------------------------+--------+
| Variable_name          | Value  |
+------------------------+--------+
| default_storage_engine | InnoDB |
+------------------------+--------+
```

Set the Default Storage Engine

Global default storage engine:

```
SET GLOBAL default_storage_engine='MyRocks';
```

Session default storage engine supersedes global default during this session:

```
SET SESSION default_storage_engine='MyRocks';
```

Configure the Default Storage Engine

```
[mariadb]
...
default_storage_engine=MyRocks
```

Identify Available Storage Engines

```
SHOW ENGINES;
```

Choose Storage Engine for a New Table

Storage engine is specified at time of table creation using a ENGINE = parameter.

```
CREATE TABLE accounts.messages (
  id INT PRIMARY KEY AUTO_INCREMENT,
  sender_id INT,
  receiver_id INT,
  message TEXT
) ENGINE = MyRocks;
```

Resources

Engines for System Tables

Standard MariaDB storage engines are used for System Table storage:

- Aria Storage Engine
- MyISAM Storage Engine

FAQ

Can I use more than one storage engine on a server?

- Yes, different tables can use different storage engines on the same server.
- To create a table with a specific storage engine, specify the ENGINE table option to the CREATE TABLE statement.

Can I use more than one storage engine in a single query?

- Yes, a single query can reference tables that use multiple storage engines.
- In some cases, special configuration may be required. For example, ColumnStore requires cross engine joins to be configured.

What storage engine should I use for transactional or OLTP workloads?

- InnoDB is the recommended storage engine for transactional or OLTP workloads.

What storage engine should I use for analytical or OLAP workloads?

- ColumnStore is the recommended storage engine for analytical or OLAP workloads.

What storage engine should I use if my application performs both transactional and analytical queries?

An application that performs both transactional and analytical queries is known as hybrid transactional-analytical processing (HTAP).

HTAP can be implemented with MariaDB by using InnoDB for transactional queries and ColumnStore for analytical queries.

Choosing the Right Storage Engine

A high-level overview of the main reasons for choosing a particular storage engine:

> **Note:**
>
> CONNECT, Mroonga, MyRocks, OQGRAPH, SphinxSE, and VIDEX are community contributions, developed and maintained by their respective contributors. Each of those engines' pages says who maintains it.

Topic List

General Purpose

- InnoDB is a good general transaction storage engine, and the best choice in most cases. It is the default storage engine.
- Aria, MariaDB's more modern improvement on MyISAM, has a small footprint and allows for easy copying between systems.
- MyISAM has a small footprint and allows for easy copying between systems. MyISAM is MySQL's oldest storage engine. There is usually little reason to use it except for legacy purposes. Aria is MariaDB's more modern improvement.
- XtraDB is no longer available. It was a performance-enhanced fork of InnoDB and was MariaDB's default engine until MariaDB 10.1.

Scaling, Partitioning

When you want to split your database load on several servers or optimize for scaling. We also suggest looking at Galera, a synchronous multi-master cluster.

- Spider uses partitioning to provide data sharding through multiple servers.
- ColumnStore utilizes a massively parallel distributed data architecture and is designed for big data scaling to process petabytes of data.
- The MERGE storage engine is a collection of identical MyISAM tables that can be used as one. "Identical" means that all tables have identical column and index information.

Compression / Archive

- MyRocks enables greater compression than InnoDB, as well as less write amplification giving better endurance of flash storage and improving overall throughput.
- The Archive storage engine is, unsurprisingly, best used for archiving.

Connecting to Other Data Sources

When you want to use data not stored in a MariaDB database.

- The CSV storage engine can read and append to files stored in CSV (comma-separated-values) format. However, since MariaDB 10.0, CONNECT is a better choice and is more flexibly able to read and write such files.

Search Optimized

Search engines optimized for search.

- SphinxSE is used as a proxy to run statements on a remote Sphinx database server (mainly useful for advanced fulltext searches).
- Mroonga provides fast CJK-ready full text searching using column store.

Cache, Read-only

- MEMORY does not write data on-disk (all rows are lost on crash) and is best-used for read-only caches of data from other tables, or for temporary work areas. With the default InnoDB and other storage engines having good caching, there is less need for this engine than in the past.

Other Specialized Storage Engines

- S3 Storage Engine is a read-only storage engine that stores its data in Amazon S3.
- Sequence allows the creation of ascending or descending sequences of numbers (positive integers) with a given starting value, ending value and increment, creating virtual, ephemeral tables automatically when you need them.
- The BLACKHOLE storage engine accepts data but does not store it and always returns an empty result. This can be useful in replication environments, for example, if you want to run complex filtering rules on a slave without incurring any overhead on a master.
- OQGRAPH allows you to handle hierarchies (tree structures) and complex graphs (nodes having many connections in several directions).
- The VIDEX storage engine is an aggregated, extensible engine suitable for what-if analyses in MariaDB. The name is derived from [VI]rtual in[DEX]. Using VIDEX, you can evaluate how potential indexes (and optimizer decisions such as join orders) would change query plans *without creating real indexes on production data*.

Alphabetical List

- The Archive storage engine is, unsurprisingly, best used for archiving.
- Aria, MariaDB's more modern improvement on MyISAM, has a small footprint and allows for easy copy between systems.
- The BLACKHOLE storage engine accepts data but does not store it and always returns an empty result. This can be useful in replication environments, for example, if you want to run complex filtering rules on a slave without incurring any overhead on a master.
- ColumnStore utilizes a massively parallel distributed data architecture and is designed for big data scaling to process petabytes of data.
- CONNECT allows access to different kinds of text files and remote resources as if they were regular MariaDB tables.
- The CSV storage engine can read and append to files stored in CSV (comma-separated-values) format. However, since MariaDB 10.0, CONNECT is a better choice and is more flexibly able to read and write such files.
- InnoDB is a good general transaction storage engine, and the best choice in most cases. It is the default storage engine.
- The MERGE storage engine is a collection of identical MyISAM tables that can be used as one. "Identical" means that all tables have identical column and index information.
- MEMORY does not write data on-disk (all rows are lost on crash) and is best-used for read-only caches of data from other tables, or for temporary work areas. With the default InnoDB and other storage engines having good caching, there is less need for this engine than in the past.
- Mroonga provides fast CJK-ready full text searching using column store.
- MyISAM has a small footprint and allows for easy copying between systems. MyISAM is MySQL's oldest storage engine. There is usually little reason to use it except for legacy purposes. Aria is MariaDB's more modern improvement.

- MyRocks enables greater compression than InnoDB, as well as less write amplification giving better endurance of flash storage and improving overall throughput.
- OQGRAPH allows you to handle hierarchies (tree structures) and complex graphs (nodes having many connections in several directions).
- S3 Storage Engine is a read-only storage engine that stores its data in Amazon S3.
- Sequence allows the creation of ascending or descending sequences of numbers (positive integers) with a given starting value, ending value and increment, creating virtual, ephemeral tables automatically when you need them.
- SphinxSE is used as a proxy to run statements on a remote Sphinx database server (mainly useful for advanced fulltext searches).
- Spider uses partitioning to provide data sharding through multiple servers.
- The VIDEX storage engine is an aggregated, extensible engine suitable for what-if analyses in MariaDB.

This page is licensed: CC BY-SA / Gnu FDL

ARCHIVE

The `ARCHIVE` storage engine is a storage engine that uses gzip to compress rows. It is mainly used for storing large amounts of data, without indexes, with only a very small footprint.

A table using the `ARCHIVE` storage engine is stored in two files on disk. There's a table definition file with an extension of .frm, and a data file with the extension .ARZ. At times during optimization, a .ARN file will appear.

New rows are inserted into a compression buffer and are flushed to disk when needed. SELECTs cause a flush. Sometimes, rows created by multi-row inserts are not visible until the statement is complete.

`ARCHIVE` allows a maximum of one key. The key must be on an AUTO_INCREMENT column, and can be a `PRIMARY KEY` or a non-unique key. However, it has a limitation: it is not possible to insert a value which is lower than the next `AUTO_INCREMENT` value.

Installing the Plugin

Although the plugin's shared library is distributed with MariaDB by default, the plugin is not actually installed by MariaDB by default. There are two methods that can be used to install the plugin with MariaDB.

The first method can be used to install the plugin without restarting the server. You can install the plugin dynamically by executing INSTALL SONAME or INSTALL PLUGIN:

```
INSTALL SONAME 'ha_archive';
```

The second method can be used to tell the server to load the plugin when it starts up. The plugin can be installed this way by providing the –plugin-load or the –plugin-load-add options. This can be specified as a command-line argument to mysqld or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
plugin_load_add = ha_archive
```

Uninstalling the Plugin

You can uninstall the plugin dynamically by executing UNINSTALL SONAME or UNINSTALL PLUGIN:

```
UNINSTALL SONAME 'ha_archive';
```

If you installed the plugin by providing the –plugin-load or the –plugin-load-add options in a relevant server option group in an option file, then those options should be removed to prevent the plugin from being loaded the next time

the server is restarted.

Characteristics

- Supports INSERT and SELECT, but not DELETE, UPDATE or REPLACE.
- Data is compressed with zlib as it is inserted, making it very small.
- Data is slow the select, as it needs to be uncompressed, and, besides the query cache, there is no cache.
- Supports AUTO_INCREMENT (since MariaDB/MySQL 5.1.6), which can be a unique or a non-unique index.
- Since MariaDB/MySQL 5.1.6, selects scan past BLOB columns unless they are specifically requested, making these queries much more efficient.
- Does not support spatial data types.
- Does not support transactions.
- Does not support foreign keys.
- Does not support virtual columns.
- No storage limit.
- Supports row locking.
- Supports table discovery, and the server can access ARCHIVE tables even if the corresponding `.frm` file is missing.
- OPTIMIZE TABLE and REPAIR TABLE can be used to compress the table in its entirety, resulting in slightly better compression.
- With MariaDB, it is possible to upgrade from the MySQL 5.0 format without having to dump the tables.
- INSERT DELAYED is supported.
- Running many SELECTs during the insertions can deteriorate the compression, unless only multi-rows INSERTs and INSERT DELAYED are used.

See The Aria Name.

A brief history of the naming of the Aria storage engine, explaining its origins as "Maria" and the reasons for the eventual name change.

This page is licensed: CC BY-SA / Gnu FDL

Aria Storage Engine

The Aria storage engine is compiled in by default from MariaDB 5.1 and it is required to be 'in use' when MariaDB is started.

All system tables are Aria.

Additionally, internal on-disk tables are in the Aria table format instead of the MyISAM table format. This should speed up some GROUP BY and DISTINCT queries because Aria has better caching than MyISAM.

Note: The ***Aria*** storage engine was previously called *Maria* (see The Aria Name for details on the rename) and in previous versions of MariaDB the engine was still called Maria.

The following table options to Aria tables in CREATE TABLE and ALTER TABLE:

- `TRANSACTIONAL= 0 | 1` : If the `TRANSACTIONAL` table option is set for an Aria table, then the table are crash-safe. This is implemented by logging any changes to the table to Aria's transaction log, and syncing those writes at the end of the statement. This will marginally slow down writes and updates. However, the benefit is that if the server dies before the statement ends, all non-durable changes will roll back to the state at the beginning of the statement. This also needs up to 6 bytes more for each row and key to store the transaction id (to allow concurrent insert's and selects).
  - `TRANSACTIONAL=1` is not supported for partitioned tables.
  - An Aria table's default value for the `TRANSACTIONAL` table option depends on the table's value for the `ROW_FORMAT` table option. See below for more details.
  - If the `TRANSACTIONAL` table option is set for an Aria table, the table does not actually support transactions. See MDEV-21364 for more information. In this context, transactional just means crash-safe.
- `PAGE_CHECKSUM= 0 | 1` : If index and data should use page checksums for extra safety.
- `TABLE_CHECKSUM= 0 | 1` :
  Same as `CHECKSUM` in MySQL 5.1
- `ROW_FORMAT=PAGE | FIXED | DYNAMIC` : The table's row format.
  - The default value is `PAGE`.
  - To emulate MyISAM, set `ROW_FORMAT=FIXED` or `ROW_FORMAT=DYNAMIC`

The `TRANSACTIONAL` and `ROW_FORMAT` table options interact as follows:

- If `TRANSACTIONAL=1` is set, then the only supported row format is `PAGE`. If `ROW_FORMAT` is set to some other value, then Aria issues a warning, but still forces the row format to be `PAGE`.
- If `TRANSACTIONAL=0` is set, then the table are not be crash-safe, and any row format is supported.
- If `TRANSACTIONAL` is not set to any value, then any row format is supported. If `ROW_FORMAT` is set, then the table will use that row format. Otherwise, the table will use the default `PAGE` row format. In this case, if the table uses the `PAGE` row format, then it are crash-safe. If it uses some other row format, then it will not be crash-safe.

Some other improvements are:

- CHECKSUM TABLE now ignores values in `NULL` fields. This makes `CHECKSUM TABLE` faster and fixes some cases where same table definition could give different checksum values depending on row format. The disadvantage is that the value is now different compared to other MySQL installations. The new checksum calculation is fixed for all table engines that uses the default way to calculate and MyISAM which does the calculation internally. Note: Old MyISAM tables with internal checksum returns the same checksum as before. To fix them to calculate according to new rules you have to do an ALTER TABLE. You can use the old ways to calculate checksums by using the option `--old` to mariadbdmysqld or set the system variable '`@@old`' to `1` when you do `CHECKSUM TABLE ... EXTENDED;`
- At startup Aria will check the Aria logs and automatically recover the tables from the last checkpoint if the server was not taken down correctly. See Aria Log Files

Startup Options for Aria

For a full list, see Aria System Variables.

In normal operations, the only variables you have to consider are:

- aria-pagecache-buffer-size
  - This is where all index and data pages are cached. The bigger this is, the faster Aria will work.
- aria-block-size
  - The default value 8192, should be ok for most cases. The only problem with a higher value is that it takes longer to find a packed key in the block as one has to search roughly 8192/2 to find each key. We plan to fix this by adding a dictionary at the end of the page to be able to do a binary search within the block before starting a scan. Until this is done and key lookups takes too long time even if you are not hitting disk, then you should consider making this smaller.
  - Possible values to try are `2048`, `4096` or `8192`
  - Note that you can't change this without dumping, deleting old tables and deleting all log files and then restoring your Aria tables. (This is the only option that requires a dump and load.)
- aria-log-purge-type
  - Set this to "`at_flush`" if you want to keep a copy of the transaction logs (good as an extra backup). The logs will stay around until you execute FLUSH ENGINE LOGS.

Aria Log Files

`aria_log_control` file is a very short log file (52 bytes) that contains the current state of all Aria tables related to logging and checkpoints. In particular, it contains the following information:

```
Aria file version: 1
Block size: 8192
maria_uuid: ee948482-6cb7-11ed-accb-3c7c3ff16468
last_checkpoint_lsn: (1,0x235a)
last_log_number: 1
trid: 28
recovery_failures: 0
```

- The `uuid` is a unique identifier per system. All Aria files created will have a copy of this in their .MAI headers. This is mainly used to check if someone has copied an Aria file between MariaDB servers.
- `last_checkpoint_lsn` and `last_log_number` are information about the current aria_log files.
- `trid` is the highest transaction number seen so far. Used by recovery.

`aria_log.*` files contain the log of all operations that change Aria files (including create table, drop table, insert etc..) This is a 'normal' WAL (Write Ahead Log), similar to the InnoDB log file, except that aria_logs contain both redo and undo. Old aria_log files are automatically deleted when they are not needed anymore (Neither the last checkpoint or any running transaction need to refer to the old data anymore).

Missing valid id

The error `Missing valid id at start of file. File is not a valid aria control file` means that something overwrote at least the first 4 bytes in the file. This can happen due to a problem with the file system (hardware or software), or a bug in which a thread inside MariaDB wrote on the wrong file descriptor (in which case you should report the bug, attaching a copy of the control file to assist).

In the case of a corrupted log file, with the server shut down, one should be able to fix that by deleting all aria_log files.
If the control_file is corrupted, then one has to delete the aria_control_file and all aria_log.* files.
The effect of this is that on table open of an Aria table, the server will think that it has been moved from another system and do an automatic check and repair of it. If there was no issues, the table are opened and can be used as normal. See also When is it safe to remove old log files.

This page is licensed: CC BY-SA / Gnu FDL

Aria Group Commit

The Aria storage engine includes a feature to group commits to speed up concurrent threads doing many inserts into the same or different Aria tables.

By default, group commit for Aria is turned off. It is controlled by the aria_group_commit and aria_group_commit_interval system variables.

Information on setting server variables can be found on the Server System Variables page.

Terminology

- A `commit` is `flush of logs` followed by a sync.
- `sent to disk` means written to disk but not sync()ed,
- `flushed` mean sent to disk and synced().
- `LSN` means log serial number. It's refers to the position in the transaction log.

Non Group commit logic (aria_group_commit="none")

The thread which first started the `commit` is performing the actual flush of logs. Other threads set the new goal (LSN) of the next pass (if it is maximum) and wait for the pass end or just wait for the pass end.

The effect of this is that a flush (write of logs + sync) will save all data for all threads/transactions that have been waiting since the last flush.

If hard group commit is enabled (aria_group_commit="hard")

If hard commit and aria_group_commit_interval=0

The first thread sends all changed buffers to disk. This is repeated as long as there are new LSNs added. The process can not loop forever because we have a limited number of threads and they will wait for the data to be synced.

Pseudo code:

```
do
   send changed buffers to disk
 while new_goal
sync
```

If hard commit and aria_group_commit_interval > 0

If less than rate microseconds has passed since the last sync, then after buffers have been sent to disk, wait until rate microseconds has passed since last sync, do sync and return.
This ensures that if we call sync infrequently we don't do any waits.

If soft group commit is enabled (aria_group_commit="soft")

Note that soft group commit should only be used if you can afford to lose a few rows if your machine shuts down hard (as in the case of a power failure).

Works like in `non group commit'` but the thread doesn't do any real sync(). If `aria_group_commit_interval` is not zero, the `sync()` calls are performed by a service thread with the given rate when needed (new LSN appears). If aria_group_commit_interval is zero, there are no `sync()` calls.

Code

The code for this can be found in `storage/maria/ma_loghandler.c::translog_flush()`.

Aria Status Variables

This page documents status variables related to the Aria storage engine. See Server Status Variables for a complete list of status variables that can be viewed with SHOW STATUS.

See also the Full list of MariaDB options, system and status variables.

`Aria_pagecache_blocks_not_flushed`

- Description: The number of dirty blocks in the Aria page cache. The global value can be flushed by FLUSH STATUS.
- Scope: Global
- Data Type: `numeric`

`Aria_pagecache_blocks_unused`

- Description: Free blocks in the Aria page cache. The global value can be flushed by FLUSH STATUS.
- Scope: Global
- Data Type: `numeric`

`Aria_pagecache_blocks_used`

- Description: Blocks used in the Aria page cache. The global value can be flushed by FLUSH STATUS.
- Scope: Global
- Data Type: `numeric`

`Aria_pagecache_read_requests`

- Description: The number of requests to read something from the Aria page cache.
- Scope: Global

- Data Type: `numeric`

`Aria_pagecache_reads`

- Description: The number of Aria page cache read requests that caused a block to be read from the disk.
- Scope: Global
- Data Type: `numeric`

`Aria_pagecache_write_requests`

- Description: The number of requests to write a block to the Aria page cache.
- Scope: Global
- Data Type: `numeric`

`Aria_pagecache_writes`

- Description: The number of blocks written to disk from the Aria page cache.
- Scope: Global
- Data Type: `numeric`

`Aria_transaction_log_syncs`

- Description: The number of Aria log fsyncs.
- Scope: Global
- Data Type: `numeric`

This page is licensed: CC BY-SA / Gnu FDL

Aria Storage Formats

The Aria storage engine supports three different table storage formats.

These are FIXED, DYNAMIC and PAGE, and they can be set with the ROW FORMAT option in the CREATE TABLE statement. PAGE is the default format, while FIXED and DYNAMIC are essentially the same as the MyISAM formats.

The SHOW TABLE STATUS statement can be used to see the storage format used by a table.

Fixed-length

Fixed-length (or static) tables contain records of a fixed-length. Each column is the same length for all records, regardless of the actual contents. It is the default format if a table has no BLOB, TEXT, VARCHAR or VARBINARY fields, and no ROW FORMAT is provided. You can also specify a fixed table with ROW_FORMAT=FIXED in the table definition.

Tables containing BLOB or TEXT fields cannot be FIXED, as by design these are both dynamic fields.

Fixed-length tables have a number of characteristics:

- fast, since MariaDB will always know where a record begins
- easy to cache
- take up more space than dynamic tables, as the maximum amount of storage space are allocated to each record.
- reconstructing after a crash is uncomplicated due to the fixed positions
- no fragmentation or need to re-organize, unless records have been deleted and you want to free the space up.

Dynamic

Dynamic tables contain records of a variable length. It is the default format if a table has any `BLOB`, `TEXT`, `VARCHAR` or `VARBINARY` fields, and no `ROW FORMAT` is provided. You can also specify a `DYNAMIC` table with `ROW_FORMAT=DYNAMIC` in the table definition.

Dynamic tables have a number of characteristics

- Each row contains a header indicating the length of the row.
- Rows tend to become fragmented easily. UPDATING a record to be longer will likely ensure it is stored in different places on the disk.
- All string columns with a length of four or more are dynamic.
- They require much less space than fixed-length tables.
- Restoring after a crash is more complicated than with `FIXED` tables.

Page

Page format is the default format for Aria tables, and is the only format that can be used if `TRANSACTIONAL=1`.

Page tables have a number of characteristics:

- It's cached by the page cache, which gives better random performance as it uses fewer system calls.
- Does not fragment as easily as the `DYNAMIC` format during `UPDATES`. The maximum number of fragments are very low.
- Updates more quickly than dynamic tables.
- Has a slight storage overhead, mainly notable on very small rows
- Slower to perform a full table scan
- Slower if there are multiple duplicated keys, as Aria will first write a row, then keys, and only then check for duplicates

Transactional

See Aria Storage Engine for the impact of the `TRANSACTIONAL` option on the row format.

This page is licensed: CC BY-SA / Gnu FDL

Aria System Variables

This page documents system variables related to the Aria storage engine. For options that are not system variables, see Aria Options.

See Server System Variables for instructions on setting system variables.

> **Note:**
>
> **For a full list of server options, system variables and status variables, see this page.**

`aria_block_size`

- Description: Block size to be used for Aria index pages. Changing this requires dumping, deleting old tables and deleting all log files, and then restoring your Aria tables. If key lookups take too long (and one has to search roughly 8192/2 by default to find each key), can be made smaller, e.g. `4096`.
- Command line: `--aria-block-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`

- Default Value: `8192`
- Range:
  - = MariaDB 10.4.7: `4096` to `32768` in increments of `1024`
  - <= MariaDB 10.4.6: `1024` to `32768` in increments of `1024`

`aria_checkpoint_interval`

- Description: Interval in seconds between automatic checkpoints. 0 means 'no automatic checkpoints' which makes sense only for testing.
- Command line: `--aria-checkpoint-interval=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `30`
- Range: `0` to `4294967295`

`aria_checkpoint_log_activity`

- Description: Number of bytes that the transaction log has to grow between checkpoints before a new checkpoint is written to the log.
- Command line: `aria-checkpoint-log-activity=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1048576`
- Range `0` to `4294967295`

`aria_encrypt_tables`

- Description: Enables automatic encryption of all user-created Aria tables that have the ROW_FORMAT table option set to PAGE. See Data at Rest Encryption and Enabling Encryption for User-created Tables.
- Command line: `aria-encrypt-tables={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`aria_force_start_after_recovery_failures`

- Description: Number of consecutive log recovery failures after which logs are automatically deleted to cure the problem; 0 (the default) disables the feature.
- Command line: `--aria-force-start-after-recovery-failures=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `0`

`aria_group_commit`

- Description: Specifies Aria group commit mode.

- Command line: `--aria_group_commit="value"`
- Alias: `maria_group_commit`
- Scope: Global
- Dynamic: No
- Data Type: `string`
- Valid values:
  - `none` - Group commit is disabled.
  - `hard` - Wait the number of microseconds specified by aria_group_commit_interval before actually doing the commit. If the interval is 0 then just check if any other threads have requested a commit during the time this commit was preparing (just before sync() file) and send their data to disk also before sync().
  - `soft` - The service thread will wait the specified time and then sync() to the log. If the interval is 0 then it won't wait for any commits (this is dangerous and should generally not be used in production)
- Default Value: `none`

`aria_group_commit_interval`

- Description: Interval between Aria group commits in microseconds (1/1000000 second) for other threads to come and do a commit in "hard" mode and sync()/commit at all in "soft" mode. Option only has effect if aria_group_commit is used.
- Command line: `--aria_group_commit_interval=#`
- Alias: `maria_group_commit_interval`
- Scope: Global
- Dynamic: No
- Type: numeric
- Valid Values:
  - Default Value: `0` (no waiting)
  - Range: `0-4294967295`

`aria_log_dir_path`

- Description: Path to the directory where transactional log should be stored
- Command line: `--aria-log-dir-path=value`
- Scope: Global
- Dynamic: No
- Data Type: `string`
- Default Value: Same as DATADIR
- Introduced: MariaDB 10.5.20, MariaDB 10.6.13, MariaDB 10.11.3 (as a system variable, existed as an option only before that)

`aria_log_file_size`

- Description: Limit for Aria transaction log size
- Command line: `--aria-log-file-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1073741824`

`aria_log_purge_type`

- Description: Specifies how the Aria transactional log are purged. Set to `at_flush` to keep a copy of the transaction logs (good as an extra backup). The logs will stay until the next FLUSH LOGS;
- Command line: `--aria-log-purge-type=name`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `immediate`
- Valid Values: `immediate`, `external`, `at_flush`

`aria_max_sort_file_size`

- Description: Don't use the fast sort index method to created index if the temporary file would get bigger than this.
- Command line: `--aria-max-sort-file-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `9223372036853727232`
- Range: `0` to `9223372036854775807`

`aria_page_checksum`

- Description: Determines whether index and data should use page checksums for extra safety. Can be overridden per table with PAGE_CHECKSUM clause in CREATE TABLE.
- Command line: `--aria-page-checksum=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`aria_pagecache_age_threshold`

- Description: This characterizes the number of hits a hot block has to be untouched until it is considered aged enough to be downgraded to a warm block. This specifies the percentage ratio of that number of hits to the total number of blocks in the page cache.
- Command line: `--aria-pagecache-age-threshold=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `300`
- Range: `100` to `9999900`

`aria_pagecache_buffer_size`

- Description: The size of the buffer used for index and data blocks for Aria tables. This can include explicit Aria tables, system tables, and temporary tables. Increase this to get better handling and measure by looking at aria-status-variables/#aria_pagecache_reads (should be small) vs aria-status-variables/#aria_pagecache_read_requests.
- Command line: `--aria-pagecache-buffer-size=#`

- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `134217728` (128MB)
- Range: `131072` (128KB) upwards

`aria_pagecache_division_limit`

- Description: The minimum percentage of warm blocks in the key cache.
- Command line: `--aria-pagecache-division-limit=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `100`
- Range: `1` to `100`

`aria_pagecache_file_hash_size`

- Description: Number of hash buckets for open and changed files. If you have many Aria files open you should increase this for faster flushing of changes. A good value is probably 1/10th of the number of possible open Aria files.
- Command line: `--aria-pagecache-file-hash-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `512`
- Range: `128` to `16384`

`aria_pagecache_segments`

- Description: The number of segments in the page_cache. Each file is put in their own segments of size pagecache_buffer_size / segments. Having many segments improves parallel performance.
- Command line: `--aria-pagecache-segments=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `1`
- Range: `1` to `128`
- Introduced: MariaDB Community Server 12.1, MariaDB Enterprise Server 11.4.8-5, MariaDB Enterprise Server 11.8

`aria_recover`

- Description: `aria_recover` has been renamed to `aria_recover_options` in MariaDB 10.2.0. See aria_recover_options for the description.

`aria_recover_options`

- Description: Specifies how corrupted tables should be automatically repaired. More than one option can be specified, for example `FORCE,BACKUP`.
  - `NORMAL`: Normal automatic repair, the default until MariaDB 10.2.3

    - `OFF`: Autorecovery is disabled, the equivalent of not using the option
    - `QUICK`: Does not check rows in the table if there are no delete blocks.
    - `FORCE`: Runs the recovery even if it determines that more than one row from the data file are lost.
    - `BACKUP`: Keeps a backup of the data files.
- Command line: `--aria-recover-options[=#]`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value:
    - `BACKUP,QUICK` (>= MariaDB 10.2.4)
    - `NORMAL` (<= MariaDB 10.2.3)
- Valid Values: `NORMAL`, `BACKUP`, `FORCE`, `QUICK`, `OFF`
- Introduced: MariaDB 10.2.0

`aria_repair_threads`

- Description: Number of threads to use when repairing Aria tables. The value of 1 disables parallel repair. Increasing from the default will usually result in faster repair, but will use more CPU and memory.
- Command line: `--aria-repair-threads=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`

`aria_sort_buffer_size`

- Description: The buffer that is allocated when sorting the index when doing a REPAIR or when creating indexes with CREATE INDEX or ALTER TABLE.
- Command line: `--aria-sort-buffer-size=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `268434432`

`aria_stats_method`

- Description: Determines how NULLs are treated for Aria index statistics purposes. If set to `nulls_equal`, all NULL index values are treated as a single group. This is usually fine, but if you have large numbers of NULLs the average group size is slanted higher, and the optimizer may miss using the index for ref accesses when it would be useful. If set to `nulls_unequal`, the default, the opposite approach is taken, with each NULL forming its own group of one. Conversely, the average group size is slanted lower, and the optimizer may use the index for ref accesses when not suitable. Setting to `nulls_ignored` ignores NULLs altogether from index group calculations. Statistics need to be recalculated after this method is changed. See also Index Statistics, myisam_stats_method and innodb_stats_method.
- Command line: `--aria-stats-method=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`

- Default Value: `nulls_unequal`
- Valid Values: `nulls_equal`, `nulls_unequal`, `nulls_ignored`

`aria_sync_log_dir`

- Description: Controls syncing directory after log file growth and new file creation.
- Command line: `--aria-sync-log-dir=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `NEWFILE`
- Valid Values: `NEWFILE`, `NEVER`, `ALWAYS`

`aria_used_for_temp_tables`

- Description: Readonly variable indicating whether the Aria storage engine is used for temporary tables. If set to `ON`, the default, the Aria storage engine is used. If set to `OFF`, MariaDB reverts to using MyISAM for on-disk temporary tables. The MEMORY storage engine is used for temporary tables regardless of this variable's setting where appropriate. The default can be changed by not using the `--with-aria-tmp-tables` option when building MariaDB.
- Command line: No
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`

`deadlock_search_depth_long`

- Description: Long search depth for the two-step deadlock detection. Only used by the Aria storage engine.
- Command line: `--deadlock-search-depth-long=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `15`
- Range: `0` to `33`

`deadlock_search_depth_short`

- Description: Short search depth for the two-step deadlock detection. Only used by the Aria storage engine.
- Command line: `--deadlock-search-depth-short=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `4`
- Range: `0` to `32`

`deadlock_timeout_long`

- Description: Long timeout in microseconds for the two-step deadlock detection. Only used by the Aria storage engine.

- Command line: `--deadlock-timeout-long=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `50000000`
- Range: `0` to `4294967295`

`deadlock_timeout_short`

- Description: Short timeout in microseconds for the two-step deadlock detection. Only used by the Aria storage engine.
- Command line: `--deadlock-timeout-short=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `10000`
- Range: `0` to `4294967295`

Aria Two-step Deadlock Detection

Description

The Aria storage engine can automatically detect and deal with deadlocks (see the Wikipedia deadlocks article).

This feature is controlled by four configuration variables, two that control the search depth and two that control the timeout.

- deadlock_search_depth_long
- deadlock_search_depth_short
- deadlock_timeout_long
- deadlock_timeout_short

How it Works

If Aria is ever unable to obtain a lock, we might have a deadlock. There are two primary ways for detecting if a deadlock has actually occurred. First is to search a wait-for graph (see the wait-for graph on Wikipedia) and the second is to just wait and let the deadlock exhibit itself. Aria Two-step Deadlock Detection does a combination of both.

First, if the lock request cannot be granted immediately, we do a short search of the wait-for graph with a small search depth as configured by the `deadlock_search_depth_short` variable. We have a depth limit because the graph can (theoretically) be arbitrarily big and we don't want to recursively search the graph arbitrarily deep. This initial, short search is very fast and most deadlocks are detected right away. If no deadlock cycles are found with the short search the system waits for the amount of time configured in `deadlock_timeout_short` to see if the lock conflicts are removed and the lock can be granted. Assuming this did not happen and the lock request still waits, the system then moves on to step two, which is a repeat of the process but this time searching deeper using the `deadlock_search_depth_long`. If no deadlock has been detected, it waits `deadlock_timeout_long` and times out.

When a deadlock is detected the system uses a weighting algorithm to determine which thread in the deadlock should be killed and then kills it.

Aria FAQ

This FAQ provides information on the Aria storage engine.

The ***Aria*** storage engine was previously known as ***Maria***, (see, the Aria Name). In current releases of MariaDB, you can refer to the engine as Maria or Aria. As this will change in future releases, please update references in your scripts and automation to use the correct name.

What is Aria?

Aria is a storage engine for MySQL® and MariaDB. It was originally developed with the goal of becoming the default transactional **and** non-transactional storage engine for MariaDB and MySQL.

It has been in development since 2007 and was first announced on Monty's blog. The same core MySQL engineers who developed the MySQL server and the MyISAM, MERGE, and MEMORY storage engines are also working on Aria.

Why is the engine called Aria?

Originally, the storage engine was called **Maria**, after Monty's younger daughter. Monty named MySQL after his first child, **My** and his second child **Max** gave his name to MaxDB and the MySQL-Max distributions.

In practice, having both *MariaDB* the database server and *Maria* the storage engine with such similar names proved confusing. To mitigate this, the decision was made to change the name. A Rename Maria contest was held during the first half of 2010 and names were submitted from around the world. Monty picked the name ***Aria*** from a short list of finalist. Chris Tooley, who suggested it, received the prize of a Linux-powered System 76 Meerkat NetTop from Monty Program.

For more information, see the Aria Name.

What's the goal for the current version?

The current version of Aria is 1.5. The goal of this release is to develop a crash-safe alternative to MyISAM. That is, when MariaDB restarts after a crash, Aria recovers all tables to the state as of the start of a statement or at the start of the last `LOCK TABLES` statement.

The current goal is to keep the code stable and fix all bugs.

What's the goal for the next version?

The next version of Aria is 2.0. The goal for this release is to develop a fully transactional storage engine with at least all the major features of InnoDB.

Currently, Aria 2.0 is on hold as its developers are focusing on improving MariaDB. However, they are interested in working with interested customers and partners to add more features to Aria and eventually release 2.0.

These are some of the goals for Aria 2.0:

- ACID compliant
- Commit/Rollback
- Concurrent updates/deletes
- Row locking
- Group commit (Already in MariaDB 5.2)
- Faster lookup in index pages (Page directory)

Beginning in Aria 2.5, the plan is to focus on improving performance.

What is the ultimate goal of Aria?

Long term, we have the following goals for Aria:

- To create a new, ACID and Multi-Version Concurrency Control (MVCC), transactional storage engine that can function as both the default non-transactional and transactional storage engine for MariaDB and MySQL®.
- To be a MyISAM replacement. This is possible because Aria can also be run in non-transactional mode, supports the same row formats as MyISAM, and supports or will support all major features of MyISAM.
- To be the default non-transactional engine in MariaDB (instead of MyISAM).

What are the design goals in Aria?

- Multi-Version Concurrency Control (MVCC) and ACID storage engine.
- Optionally non-transactional tables that should be 'as fast and as compact' as MyISAM tables.
- Be able to use Aria for internal temporary tables in MariaDB (instead of MyISAM).
- All indexes should have equal speed (clustered index is not on our current road map for Aria. If you need clustered index, you should use XtraDB).
- Allow 'any' length transactions to work (Having long running transactions will cause more log space to be used).
- Allow log shipping; that is, you can do incremental backups of Aria tables just by copying the Aria logs.
- Allow copying of Aria tables between different Aria servers (under some well-defined constraints).
- Better blob handling (than is currently offered in MyISAM, at a minimum).
- No memory copying or extra memory used for blobs on insert/update.
- Blobs allocated in big sequential blocks - Less fragmentation over time.
- Blobs are stored so that Aria can easily be extended to have access to any part of a blob with a single fetch in the future.
- Efficient storage on disk (that is, low row data overhead, low page data overhead and little lost space on pages). Note: There is still some more work to succeed with this goal. The disk layout is fine, but we need more in-memory caches to ensure that we get a higher fill factor on the pages.
- Small footprint, to make MariaDB + Aria suitable for desktop and embedded applications.
- Flexible memory allocation and scalable algorithms to utilize large amounts of memory efficiently, when it is available.

Where can I find documentation and help about Aria?

Documentation is available at Aria and related topics. The project is maintained on GitHub.

If you want to know what happens or be part of developing Aria, you can subscribe to the developers, docs, or discuss mailing lists.

To report and check bugs in Aria, see Reporting Bugs.

You can usually find some of the Maria developers on our Zulip instance at mariadb.zulipchat.com or on the IRC channel #maria at.

Who develops Aria?

The Core Team who develop Aria are:

Technical lead

- Michael "Monty" Widenius - Creator of MySQL and MyISAM

Core Developers (in alphabetical order)

- Guilhem Bichot - Replication expert, on line backup for MyISAM, etc.
- Kristian Nielsen - MySQL build tools, NDB, MySQL server

- Oleksandr Byelkin - Query cache, sub-queries, views.
- Sergei Golubchik - Server Architect, Full text search, keys for MyISAM-Merge, Plugin architecture, etc.

All except Guilhem Bichot are working for MariaDB Corporation Ab.

What is the release policy/schedule of Aria?

Aria follows the same release criteria as for MariaDB. Some clarifications, unique for the Aria storage engine:

- Aria index and data file formats should be backwards and forwards compatible to ensure easy upgrades and downgrades.
- The log file format should also be compatible, but we don't make any guarantees yet. In some cases when upgrading, you must remove the old `aria_log.%` and `maria_log.%` files before restarting MariaDB. (So far, this has only occurred in the upgrade from MariaDB 5.1 and MariaDB 5.2).

Extended commitment for Beta 1.5

- Aria is now feature complete according to specification.

How does Aria 1.5 Compare to MyISAM?

Aria 1.0 was basically a crash-safe non-transactional version of MyISAM. Aria 1.5 added more concurrency (multiple inserter) and some optimizations.

Aria supports all aspects of MyISAM, except as noted below. This includes external and internal check/repair/compressing of rows, different row formats, different index compress formats, aria_chk etc. After a normal shutdown you can copy Aria files between servers.

Advantages of Aria compared to MyISAM

- Data and indexes are crash safe.
- On a crash, changes are rolled back to state of the start of a statement or a last `LOCK TABLES` statement.
- Aria can replay almost everything from the log. (Including `CREATE`, `DROP`, `RENAME`, `TRUNCATE` tables). Therefore, you make a backup of Aria by just copying the log. The things that can't be replayed (yet) are:
  - Batch `INSERT` into an empty table (This includes `LOAD DATA INFILE`, `SELECT... INSERT` and `INSERT` (many rows)).
  - `ALTER TABLE`. Note that `.frm` tables are NOT recreated!
- `LOAD INDEX` can skip index blocks for unwanted indexes.
- Supports all MyISAM `ROW` formats and new `PAGE` format where data is stored in pages. (default size is 8K).
- Multiple concurrent inserters into the same table.
- When using `PAGE` format (default) row data is cached by page cache.
- Aria has unit tests of most parts.
- Supports both crash-safe (soon to be transactional) and not transactional tables. (Non-transactional tables are not logged and rows uses less space): `CREATE TABLE foo (...) TRANSACTIONAL=0|1 ENGINE=Aria`.
- `PAGE` is the only crash-safe/transactional row format.
- `PAGE` format should give a notable speed improvement on systems which have bad data caching. (For example Windows).
- From MariaDB 10.5, max key length is 2000 bytes, compared to 1000 bytes in MyISAM.

Differences between Aria and MyISAM

- Aria uses BIG (1G by default) log files.

- Aria has a log control file (`aria_log_control`) and log files (`aria_log.%`). The log files can be automatically purged when not needed or purged on demand (after backup).
- Aria uses 8K pages by default (MyISAM uses 1K). This makes Aria a bit faster when using keys of fixed size, but slower when using variable-length packed keys (until we add a directory to index pages).

Disadvantages of Aria compared to MyISAM

- Aria doesn't support `INSERT DELAYED`.
- Aria does not support multiple key caches.
- Storage of very small rows (< 25 bytes) are not efficient for `PAGE` format.
- `MERGE` tables don't support Aria (should be very easy to add later).
- Aria data pages in block format have an overhead of 10 bytes/page and 5 bytes/row. Transaction and multiple concurrent-writer support will use an extra overhead of 7 bytes for new rows, 14 bytes for deleted rows and 0 bytes for old compacted rows.
- No external locking (MyISAM has external locking, but this is a rarely used feature).
- Aria has one page size for both index and data (defined when Aria is used the first time). MyISAM supports different page sizes per index.
- Small overhead (15 bytes) per index page.
- Aria doesn't support MySQL internal RAID (disabled in MyISAM too, it's a deprecated feature).
- Minimum data file size for PAGE format is 16K (with 8K pages).
- Aria doesn't support indexes on virtual fields.

Differences between MariaDB 5.1 release and the normal MySQL-5.1 release?

See:

- Aria storage engine
- MariaDB versus MySQL

Why do you use the `TRANSACTIONAL` keyword now when Aria is not yet transactional?

In the current development phase Aria tables created with `TRANSACTIONAL=1` are crash safe and atomic but not transactional because changes in Aria tables can't be rolled back with the `ROLLBACK` command. As we planned to make Aria tables fully transactional, we decided it was better to use the `TRANSACTIONAL` keyword from the start so that applications don't need to be changed later.

What are the known problems with the MySQL-5.1-Maria release?

- See `KNOWN_BUGS.txt` for open/design bugs.
- See jira.mariadb.org for newly reported bugs. Please report anything you can't find here!
- If there is a bug in the Aria recovery code or in the code that generates the logs, or if the logs become corrupted, then mysqld may fail to start because Aria can't execute the logs at start up.
- Query cache and concurrent insert using page row format have a bug, please disable query cache while using page row format and MDEV-6817 isn't complete

If Aria doesn't start or you have an unrecoverable table (shouldn't happen):

- Remove the `aria_log.%` files from the data directory.
- Restart `mysqld` and run CHECK TABLE, REPAIR TABLE or mariadb-check on your Aria tables.

Alternatively,

- Remove logs and run aria_chk on your `*.MAI` files.

What is going to change in later Aria main releases?

The `LOCK TABLES` statement will not start a crash-safe segment. You should use begin and COMMIT instead.

To make things future safe, you could do this:

```
BEGIN;
LOCK TABLES ....
UNLOCK TABLES;
COMMIT;
```

And later you can just remove the `LOCK TABLES` and `UNLOCK TABLES` statements.

How can I create a MyISAM-like (non-transactional) table in Aria?

Example:

```
CREATE TABLE t1 (a INT) ROW_FORMAT=FIXED TRANSACTIONAL=0 PAGE_CHECKSUM=0;
CREATE TABLE t2 (a INT) ROW_FORMAT=DYNAMIC TRANSACTIONAL=0 PAGE_CHECKSUM=0;
SHOW CREATE TABLE t1;
SHOW CREATE TABLE t2;
```

Note that the rows are not cached in the page cache for `FIXED` or `DYNAMIC` format. If you want to have the data cached (something MyISAM doesn't support) you should use `ROW_FORMAT=PAGE`:

```
CREATE TABLE t3 (a INT) ROW_FORMAT=PAGE TRANSACTIONAL=0 PAGE_CHECKSUM=0;
SHOW CREATE TABLE t3;
```

You can use `PAGE_CHECKSUM=1` also for non-transactional tables; This puts a page checksums on all index pages. It also puts a checksum on data pages if you use `ROW_FORMAT=PAGE`.

You may still have a speed difference (may be slightly positive or negative) between MyISAM and Aria because of different page sizes. You can change the page size for MariaDB with `--aria-block-size=\#`, where `\`

is 1024, 2048, 4096, 8192, 16384 or 32768.

Note that if you change the page size you have to dump all your old tables into text (with mariadb-dump) and remove the old Aria log and files:

```
# rm datadir/aria_log*
```

What are the advantages/disadvantages of the new `PAGE` format compared to the old MyISAM-like row formats (`DYNAMIC` and `FIXED`)

The MyISAM-like `DYNAMIC` and `FIXED` format are extremely simple and have very little space overhead, so it's hard to beat them for when it comes to simple scanning of unmodified data. The `DYNAMIC` format does however get notably worse over time if you update the row a lot in a manner that increases the size of the row.

The advantages of the `PAGE` format (compared to `DYNAMIC` or `FIXED`) for non-transactional tables are:

- It's cached by the Page Cache, which gives better random performance (as it uses less system calls).
- Does not fragment as easily as the `DYNAMIC` format during `UPDATE` statements. The maximum number of fragments are very low.
- Code can easily be extended to only read the accessed columns (for example to skip reading blobs).
- Faster updates (compared to `DYNAMIC`).

The disadvantages are:

- Slight storage overhead (should only be notable for very small row sizes)

- Slower full table scan time.
- When using `row_format=PAGE`, (the default), Aria first writes the row, then the keys, at which point the check for duplicate keys happens. This makes `PAGE` format slower than `DYNAMIC` (or MyISAM) if there is a lot of duplicated keys because of the overhead of writing and removing the row. If this is a problem, you can use `row_format=DYNAMIC` to get same behavior as MyISAM.

What's the proper way to copy a Aria table from one place to another?

An Aria table consists of 3 files:

```
XXX.frm : The definition for the table, used by MySQL.
XXX.MYI : Aria internal information about the structure of the data and index and data for all indexes.
XXX.MAD : The data.
```

It's safe to copy all the Aria files to another directory or MariaDB instance if any of the following holds:

- If you shutdown the MariaDB Server properly with mariadb-admin shutdown, so that there is nothing for Aria to recover when it starts.

or

- If you have run a FLUSH TABLES statement and not accessed the table using SQL from that time until the tables have been copied.

In addition, you must adhere the following rule for transactional tables:

You can't copy the table to a location within the same MariaDB server if the new table has existed before and the new table is still active in the Aria recovery log (that is, Aria may need to access the old data during recovery). If you are unsure whether the old name existed, run aria_chk –zerofill on the table before you use it.

After copying a transactional table and before you use the table, we recommend that you run the command:

```
$ aria_chk --zerofill table_name
```

This will overwrite all references to the logs (LSN), all transactional references (TRN) and all unused space with 0. It also marks the table as 'movable'. An additional benefit of zerofill is that the Aria files will compress better. No real data is ever removed as part of zerofill.

Aria will automatically notice if you have copied a table from another system and do 'zerofill' for the first access of the table if it was not marked as 'movable'. The reason for using aria_chk –zerofill is that you avoid a delay in the MariaDB server for the first access of the table.

Note that this automatic detection doesn't work if you copy tables within the same MariaDB server!

When is it safe to remove old log files?

If you want to remove the Aria log files (`aria_log.%`) with `rm` or delete, then you must first shut down MariaDB cleanly (for example, with mariadb-admin shutdown) before deleting the old files.

The same rules apply when upgrading MariaDB; When upgrading, first take down MariaDB in a clean way and then upgrade. This will allow you to remove the old log files if there are incompatible problems between releases.

Don't remove the `aria_log_control` file! This is not a log file, but a file that contains information about the Aria setup (current transaction id, unique id, next log file number etc.).

If you do, Aria will generate a new `aria_log_control` file at startup and will regard all old Aria files as files moved from another system. This means that they have to be 'zerofilled' before they can be used. This will happen automatically at next access of the Aria files, which can take some time if the files are big.

If this happens, you will see things like this in your mysqld.err file:

```
[Note] Zerofilling moved table: '.\database\xxxx'
```

As part of zerofilling no vital data is removed.

How does one solve the Missing valid id error?

See Aria Log Files for details.

The Aria Name

The Aria storage engine used to be called Maria. This page gives the history and background of how and why this name was changed to Aria.

Backstory

When starting what became the MariaDB project, Monty and the initial developers only planned to work on a next generation MyISAM storage engine replacement.
This storage engine would be crash safe and eventually support transactions.
Monty named the storage engine, and the project, after his daughter, Maria.

Work began in earnest on the Maria storage engine but the plans quickly expanded and morphed and soon the developers were not just working on a storage engine, but on a complete branch of the MySQL database. Since the project was already called Maria, it made sense to call the whole database server MariaDB.

Renaming Maria (the engine)

So now there was the database, MariaDB, and the storage engine, Maria. To end the confusion this caused, the decision was made to rename the storage engine.

Monty's first suggestion was to name it *Lucy*, after his dog, but few who heard it liked that idea. So the decision was made that the next best thing was for the community to suggest and vote on names.

This was done by running a contest in 2009 through the end of May 2010.
After that the best names were voted on by the community and Monty picked and announced the winner (Aria) at OSCon 2010 in Portland.

The winning entry was submitted by Chris Tooley. He received a Linux-powered System 76 Meerkat NetTop as his prize for suggesting the winning name from Monty Program.

BLACKHOLE

The `BLACKHOLE` storage engine accepts data but does not store it and always returns an empty result.

A table using the `BLACKHOLE` storage engine consists of a single .frm table format file, but no associated data or index files.

This storage engine can be useful, for example, if you want to run complex filtering rules on a slave without incurring any overhead on a master. The master can run a `BLACKHOLE` storage engine, with the data replicated to the slave for processing.

Installing the Plugin

Although the plugin's shared library is distributed with MariaDB by default, the plugin is not actually installed by MariaDB by default. There are two methods that can be used to install the plugin with MariaDB.

The first method can be used to install the plugin without restarting the server. You can install the plugin dynamically by executing INSTALL SONAME or INSTALL PLUGIN:

```
INSTALL SONAME 'ha_blackhole';
```

The second method can be used to tell the server to load the plugin when it starts up. The plugin can be installed this way by providing the –plugin-load or the –plugin-load-add options. This can be specified as a command-line argument to mysqld or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
plugin_load_add = ha_blackhole
```

Uninstalling the Plugin

You can uninstall the plugin dynamically by executing UNINSTALL SONAME or UNINSTALL PLUGIN:

```
UNINSTALL SONAME 'ha_blackhole';
```

If you installed the plugin by providing the –plugin-load or the –plugin-load-add options in a relevant server option group in an option file, then those options should be removed to prevent the plugin from being loaded the next time the server is restarted.

Using the BLACKHOLE Storage Engine

Using with DML

INSERT, UPDATE, and DELETE statements all work with the `BLACKHOLE` storage engine. However, no data changes are actually applied.

Using with Replication

If the binary log is enabled, all SQL statements are logged as usual, and replicated to any slave servers. However, since rows are not stored, it is important to use statement-based rather than the row or mixed format, as UPDATE and DELETE statements are neither logged nor replicated. See Binary Log Formats.

Using with Triggers

Some triggers work with the `BLACKHOLE` storage engine.

`BEFORE` triggers for INSERT statements are still activated.

Triggers for UPDATE and DELETE statements are **not** activated.

Triggers with the `FOR EACH ROW` clause do not apply, since the tables have no rows.

Using with Foreign Keys

Foreign keys are not supported. If you convert an InnoDB table to `BLACKHOLE`, then the foreign keys will disappear. If you convert the same table back to InnoDB, then you will have to recreate them.

Using with Virtual Columns

If you convert an InnoDB table which contains virtual columns to `BLACKHOLE`, then it produces an error.

Using with AUTO_INCREMENT

Because a BLACKHOLE table does not store data, it will not maintain the AUTO_INCREMENT value. If you are replicating to a table that can handle `AUTO_INCREMENT` columns, and are not explicitly setting the primary key auto-increment value in the INSERT query, or using the SET INSERT_ID statement, inserts will fail on the slave due to duplicate keys.

Limits

The maximum key size is:

- 3500 bytes (>= MariaDB 10.1.48, MariaDB 10.2.35, MariaDB 10.3.26, MariaDB 10.4.16 and MariaDB 10.5.7)
- 1000 bytes (<= MariaDB 10.1.47, MariaDB 10.2.34, MariaDB 10.3.25, MariaDB 10.4.15 and MariaDB 10.5.6).

Examples

```
CREATE TABLE table_name (
   id INT UNSIGNED PRIMARY KEY NOT NULL,
   v VARCHAR(30)
) ENGINE=BLACKHOLE;

INSERT INTO table_name VALUES (1, 'bob'),(2, 'jane');

SELECT * FROM table_name;
Empty set (0.001 sec)
```

Connect 1.04.0003	MariaDB 10.1.9	Beta

The CONNECT storage engine enables MariaDB to access external local or remote data (MED). This is done by defining tables based on different data types, in particular files in various formats, data extracted from other DBMS or products (such as Excel or MongoDB) via ODBC or JDBC, or data retrieved from the environment (for example DIR, WMI, and MAC tables)

This storage engine supports table partitioning, MariaDB virtual columns and permits defining *special* columns such as `ROWID`, `FILEID`, and `SERVID`.

No precise definition of maturity exists. Because CONNECT handles many table types, each type has a different maturity depending on whether it is old and well-tested, less well-tested or newly implemented. This is indicated for all data types.

Introduction to the CONNECT Engine

CONNECT is not just a new “YASE” (Yet another Storage Engine) that provides another way to store data with additional features. It brings a new dimension to MariaDB, already one of the best products to deal with traditional database transactional applications, further into the world of business intelligence and data analysis, including NoSQL facilities. Indeed, BI is the set of techniques and tools for the transformation of raw data into meaningful and useful information. And where is this data?

> “It’s amazing in an age where relational databases reign supreme when it comes to managing data that so much information still exists outside RDBMS engines in the form of flat files and other such constructs. In most enterprises, data is passed back and forth between disparate systems in a fashion and speed that would rival the busiest expressways in the world, with much of this data existing in common, delimited files. Target systems intercept these source files and then typically proceed to load them via ETL (extract, transform, load) processes into databases that then utilize the information for business intelligence, transactional functions, or other standard operations. ETL tasks and data movement jobs can consume quite a bit of time and resources, especially if large volumes of data are present that require loading into a database.
> This being the case, many DBAs welcome alternative means of accessing and managing data that exists in file format.”

- Robin Schumacher[1]

What he describes is known as MED (Management of External Data) enabling the handling of data not stored in a DBMS database as if it were stored in tables. An ISO standard exists that describes one way to implement and use MED in SQL by defining foreign tables for which an external FDW (Foreign Data Wrapper) has been developed in C.

However, since this was written, a new source of data was developed as the “cloud”. Data are existing worldwide and, in particular, can be obtained in JSON or XML format in answer to REST queries. From Connect 1.06.0010, it is possible to create JSON, XML or CSV tables based on data retrieved from such REST queries.

MED as described above is a rather complex way to achieve this goal and MariaDB does not support the ISO SQL/MED standard. But, to cover the need, possibly in transactional but mostly in decision support applications, the CONNECT storage engine supports MED in a much simpler way.

The main features of CONNECT are:

1. No need for additional SQL language extensions.
2. Embedded wrappers for many external data types (files, data sources, virtual).
3. NoSQL query facilities for JSON, XML, HTML files and using JSON UDFs.
4. NoSQL data obtained from REST queries (requires cpprestsdk).
5. NoSQL new data type MONGO accessing MongoDB collections as relational tables.
6. Read/Write access to external files of most commonly used formats.
7. Direct access to most external data sources via ODBC, JDBC and MySQL or MongoDB API.
8. Only used columns are retrieved from external scan.
9. Push-down WHERE clauses when appropriate.
10. Support of special and virtual columns.
11. Parallel execution of multi-table tables (currently unavailable).
12. Supports partitioning by sub-files or by sub-tables (enabling table sharding).
13. Support of MRR for SELECT, UPDATE and DELETE.
14. Provides remote, block, dynamic and virtual indexing.
15. Can execute complex queries on remote servers.
16. Provides an API that allows writing additional FDW in C++.

With CONNECT, MariaDB has one of the most advanced implementations of MED and NoSQL, without the need for complex additions to the SQL syntax (foreign tables are “normal” tables using the CONNECT engine).

Giving MariaDB easy and natural access to external data enables the use of all of its powerful functions and SQL-handling abilities for developing business intelligence applications.

With version 1.07 of CONNECT, retrieving data from REST queries is available in all binary distributed version of MariaDB, and, from 1.07.002, CONNECT allows workspaces greater than 4GB.

Using CONNECT - Condition Pushdown

The ODBC, JDBC, MYSQL, TBL and WMI table types use engine condition pushdown in order to restrict the number of rows returned by the RDBS source or the WMI component.

The CONDITION_PUSHDOWN argument used in old versions of CONNECT is no longer needed because CONNECT uses condition pushdown unconditionally.

This page is licensed: GPLv2

Using CONNECT - Exporting Data From MariaDB

Exporting data from MariaDB is obviously possible with CONNECT in particular for all formats not supported by the SELECT INTO OUTFILE statement. Let us consider the query:

```
SELECT
    plugin_name AS handler,
    plugin_version AS version,
    plugin_author AS author,
    plugin_description AS description,
    plugin_maturity AS maturity
FROM
    information_schema.plugins
WHERE
    plugin_type = 'STORAGE ENGINE';
```

Supposing you want to get the result of this query into a file handlers.htm in XML/HTML format, allowing displaying it on an Internet browser, this is how you can do it:

Just create the CONNECT table that are used to make the file:

```
CREATE TABLE handout
ENGINE=CONNECT
table_type=XML
file_name='handout.htm'
header=yes
option_list='name=TABLE,coltype=HTML,attribute=border=1;cellpadding=5,headattr=bgcolor=yellow'
AS
SELECT
    plugin_name AS handler,
    plugin_version AS version,
    plugin_author AS author,
    plugin_description AS description,
    plugin_maturity AS maturity
FROM
    information_schema.plugins
WHERE
    plugin_type = 'STORAGE ENGINE';
```

Here the column definition is not given and will come from the Select statement following the Create. The CONNECT options are the same we have seen previously. This will do both actions, creating the matching *handlers* CONNECT table and 'filling' it with the query result.

Note 1: This could not be done in only one statement if the table type had required using explicit CONNECT column options. In this case, firstly create the table, and then populate it with an Insert statement.

Note 2: The source "plugins" table column "description" is a long text column, data type not supported for CONNECT tables. It has been silently internally replaced by varchar(256).

This page is licensed: GPLv2

Using CONNECT - General Information

The main characteristic of CONNECT is to enable accessing data scattered on a machine as if it was a centralized database. This, and the fact that locking is not used by connect (data files are open and closed for each query) makes CONNECT very useful for importing or exporting data into or from a MariaDB database and also for all types of Business Intelligence applications. However, it is not suited for transactional applications.

For instance, the index type used by CONNECT is closer to bitmap indexing than to B-trees. It is very fast for retrieving result but not when updating is done. In fact, even if only one indexed value is modified in a big table, the index is entirely remade (yet this being four to five times faster than for a b-tree index). But normally in Business Intelligence applications, files are not modified so often.

If you are using CONNECT to analyze files that can be modified by an external process, the indexes are of course not modified by it and become outdated. Use the OPTIMIZE TABLE command to update them before using the tables based on them.

This means also that CONNECT is not designed to be used by centralized servers, which are mostly used for transactions and often must run a long time without human intervening.

Performance

Performances vary a great deal depending on the table type. For instance, ODBC tables are only retrieved as fast as the other DBMS can do. If you have a lot of queries to execute, the best way to optimize your work can be sometime to translate the data from one type to another. Fortunately this is very simple with CONNECT. Fixed formats like FIX, BIN or VEC tables can be created from slower ones by commands such as:

```
CREATE TABLE fastable table_specs SELECT * FROM slowtable;
```

`FIX` and `BIN` are often the better choice because the I/O functions are done on blocks of `BLOCK_SIZE` rows. `VEC` tables can be very efficient for tables having many columns only a few being used in each query. Furthermore, for tables of reasonable size, the `MAPPED` option can very often speed up many queries.

Create Table statement

Be aware of the two broad kinds of CONNECT tables:

Inward	They are table whose file name is not specified at create. An empty file are given a default name (tabname.tabtype) and are populated like for other engines. They do not require the FILE privilege and can be used for testing purpose.
Outward	They are all other CONNECT tables and access external data sources or files. They are the true useful tables but require the FILE privilege.

Drop Table statement

For outward tables, the DROP TABLE statement just removes the table definition but does not erase the table data. However, dropping an inward tables also erase the table data as well.

Alter Table statement

Be careful using the ALTER TABLE statement. Currently the data compatibility is not tested and the modified definition can become incompatible with the data. In particular, Alter modifies the table definition only but does not modify the table data. Consequently, the table type should not be modified this way, except to correct an incorrect definition. Also adding, dropping or modifying columns may be wrong because the default offset values (when not explicitly given by the FLAG option) may be wrong when recompiled with missing columns.

Safe use of ALTER is for indexing, as we have seen earlier, and to change options such as MAPPED or HUGE those do not impact the data format but just the way the data file is accessed. Modifying the BLOCK_SIZE option is all right with FIX, BIN, DBF, split VEC tables; however it is unsafe for VEC tables that are not split (only one data file) because at their creation the estimate size has been made a multiple of the block size. This can cause errors if this estimate is not a multiple of the new value of the block size.

In all cases, it is safer to drop and re-create the table (outward tables) or to make another one from the table that must be modified.

Update and Delete for File Tables

CONNECT can execute these commands using two different algorithms:

- It can do it in place, directly modifying rows (update) or moving rows (delete) within the table file. This is a fast way to do it in particular when indexing is used.

- It can do it using a temporary file to make the changes. This is required when updating variable record length tables and is more secure in all cases.

The choice between these algorithms depends on the session variable connect_use_tempfile.

This page is licensed: GPLv2

Using CONNECT - Importing File Data Into MariaDB Tables

Directly using external (file) data has many advantages, such as to work on “fresh” data produced for instance by cash registers, telephone switches, or scientific apparatus. However, you may want in some case to import external data into your MariaDB database. This is extremely simple and flexible using the CONNECT handler. For instance, let us suppose you want to import the data of the xsample.xml XML file previously given in example into a MyISAM table called *biblio* belonging to the connect database. All you have to do is to create it by:

```
CREATE TABLE biblio ENGINE=myisam SELECT * FROM xsampall2;
```

This last statement creates the MyISAM table and inserts the original XML data, translated to tabular format by the *xsampall2* CONNECT table, into the MariaDB *biblio* table. Note that further transformation on the data could have been achieved by using a more elaborate Select statement in the Create statement, for instance using filters, alias or applying functions to the data. However, because the Create Table process copies table data, later modifications of the *xsample.xml* file will not change the *biblio* table and changes to the *biblio* table will not modify the *xsample.xml* file.

All these can be combined or transformed by further SQL operations. This makes working with CONNECT much more flexible than just using the LOAD statement.

This page is licensed: GPLv2

Using CONNECT - Indexing

> **Warning:**
>
> This storage engine has been deprecated.

Indexing is one of the main ways to optimize queries. Key columns, in particular when they are used to join tables, should be indexed. But what should be done for columns that have only few distinct values? If they are randomly placed in the table they should not be indexed because reading many rows in random order can be slower than reading the entire table sequentially. However, if the values are sorted or clustered, indexing can be acceptable because CONNECT indexes store the values in the order they appear into the table and this will make retrieving them almost as fast as reading them sequentially.

CONNECT provides four indexing types:

1. Standard Indexing
2. Block Indexing
3. Remote Indexing
4. Dynamic Indexing

Standard Indexing

CONNECT standard indexes are created and used as the ones of other storage engines although they have a specific internal format. The CONNECT handler supports the use of standard indexes for most of the file based table types.

You can define them in the CREATE TABLE statement, or either using the `CREATE INDEX` statement or the ALTER TABLE statement. In all cases, the index files are automatically made. They can be dropped either using the DROP

INDEX statement or the ALTER TABLE statement, and this erases the index files.

Indexes are automatically reconstructed when the table is created, modified by `INSERT`, `UPDATE` or `DELETE` statements, or when the `SEPINDEX` option is changed. If you have a lot of changes to do on a table at one moment, you can use table locking to prevent indexes to be reconstructed after each statement. The indexes are reconstructed when unlocking the table. For instance:

```
LOCK TABLE t1 WRITE;
INSERT INTO t1 VALUES(...);
INSERT INTO t1 VALUES(...);
...
UNLOCK TABLES;
```

If a table was modified by an external application that does not handle indexing, the indexes must be reconstructed to prevent returning false or incomplete results. To do this, use the OPTIMIZE TABLE command.

For outward tables, index files are not erased when dropping the table. This is the same as for the data file and preserves the possibility of several users using the same data file via different tables.

Unlike other storage engines, CONNECT constructs the indexes as files that are named by default from the data file name, not from the table name, and located in the data file directory. Depending on the `SEPINDEX` table option, indexes are saved in a unique file or in separate files (if `SEPINDEX` is true). For instance, if indexes are in separate files, the primary index of the `table_dept.dat_` of type `DOS` is a file named *`dept_PRIMARY.dnx`*. This makes possible to define several tables on the same data file, with eventual different options such as mapped or not mapped, and to share the index files as well.

If the index file should have a different name, for instance because several tables are created on the same data file with different indexes, specify the base index file name with the `XFILE_NAME` option.

Note1: Indexed columns must be declared `NOT NULL`; CONNECT doesn't support indexes containing null values.

Note 2: MRR is used by standard indexing if it is enabled.

Note 3: Prefix indexing is not supported. If specified, the CONNECT engine ignores the prefix and builds a whole index.

Handling index errors

The way CONNECT handles indexing is very specific. All table modifications are done regardless of indexing. Only after a table has been modified, or when an `OPTIMIZE TABLE` command is sent are the indexes made. If an error occurs, the corresponding index is not made. However, CONNECT being a non-transactional engine, it is unable to roll back the changes made to the table. The main causes of indexing errors are:

- Trying to index a nullable column. In this case, you can alter the table to declare the column as not nullable or, if the column is nullable indeed, make it not indexed.
- Entering duplicate values in a column indexed by a unique index. In this case, if the index was wrongly declared as unique, alter is declaration to reflect this. If the column should really contain unique values, you must manually remove or update the duplicate values.

In both cases, after correcting the error, remake the indexes with the OPTIMIZE TABLE command.

Index file mapping

To accelerate the indexing process, CONNECT makes an index structure in memory from the index file. This can be done by reading the index file or using it as if it was in memory by "file mapping". On enabled versions, file mapping is used according to the boolean connect_indx_map system variable. Set it to 0 (file read) or 1 (file mapping).

Block Indexing

To accelerate input/output, CONNECT uses when possible a read/write mode by blocks of n rows, n being the value given in the BLOCK _ SIZE option of the Create Table, or a default value depending on the table type. This is automatic for fixed files (FIX, BIN, DBF or VEC), but must be specified for variable files (DOS , CSV or FMT).

For blocked tables, further optimization can be achieved if the data values for some columns are "clustered" meaning that they are not evenly scattered in the table but grouped in some consecutive rows. Block indexing permits to skip blocks in which no rows fulfill a conditional predicate without having even to read the block. This is true in particular for sorted columns.

You indicate this when creating the table by using the DISTRIB =d column option. The enum value d can be *scattered*, *clustered*, or *sorted*. In general only one column can be sorted. Block indexing is used only for clustered and sorted columns.

Difference between standard indexing and block indexing

- Block indexing is internally handled by CONNECT while reading sequentially a table data. This means in particular that when standard indexing is used on a table, block indexing is not used.
- In a query, only one standard index can be used. However, block indexing can combine the restrictions coming from a where clause implying several clustered/sorted columns.
- The block index files are faster to make and much smaller than standard index files.

Notes for this Release:

- On all operations that create or modify a table, CONNECT automatically calculates or recalculates and saves the mini/maxi or bitmap values for each block, enabling it to skip block containing no acceptable values. In the case where the optimize file does not correspond anymore to the table, because it has been accidentally destroyed, or because some column definitions have been altered, you can use the `OPTIMIZE TABLE` command to reconstruct the optimization file.
- Sorted column special processing is currently restricted to ascending sort. Column sorted in descending order must be flagged as clustered. Improper sorting is not checked in Update or Insert operations but is flagged when optimizing the table.
- Block indexing can be done in two ways. Keeping the min/max values existing for each block, or keeping a bitmap allowing knowing what column distinct values are met in each blocks. This second ways often gives a better optimization, except for sorted columns for which both are equivalent. The bitmap approach can be done only on columns having not too many distinct values. This is estimated by the `MAX_DIST` option value associated to the column when creating the table. Bitmap block indexing are used if this number is not greater than the `MAXBMP` setting for the database.
- CONNECT cannot perform block indexing on case insensitive character columns. To force block indexing on a character column, specify its charset as not case insensitive, for instance as binary.
  However this will also apply to all other clauses, this column being now case sensitive.

Remote Indexing

Remote indexing is specific to the MYSQL table type. It is equivalent to what the FEDERATED storage does. A MYSQL table does not support indexes per se. Because access to the table is handled remotely, it is the remote table that supports the indexes. What the MYSQL table does is just to add a WHERE clause to the SELECT command sent to the remote server allowing the remote server to use indexing when applicable.

Note, however, that because CONNECT adds when possible all or part of the where clause of the original query, this happens often even if the remote indexed column is not declared locally indexed.
The only, but very important, case a column should be locally declared indexed is when it is used to join tables. Otherwise, the required where clause would not be added to the sent `SELECT` query.

See Indexing of MYSQL tables for more.

Dynamic Indexing

An indexed created as “dynamic” is a standard index which, in some cases, can be reconstructed for a specific query. This happens in particular for some queries where two tables are joined by an indexed key column. If the “from” table is big and the “to” big table reduced in size because of a where clause, it can be worthwhile to reconstruct the index on this reduced table.

Because of the time added by reconstructing the index, this is valuable only if the time gained by reducing the index size if more than this reconstruction time. This is why this should not be done if the “from” table is small because there will not be enough row joining to compensate for the additional time.
Otherwise, the gain of using a dynamic index is:

- Indexing time is a little faster if the index is smaller.
- The join process will return only the rows fulfilling the where clause.
- Because the table is read sequentially when reconstructing the index there no need for MRR.
- Constructing the index can be faster if the table is reduced by block indexing.
- While constructing the index, CONNECT also stores in memory the values of other used columns.

This last point is particularly important. It means that after the index is reconstructed, the join is done on a temporary memory table.

Unfortunately, storage engines being called independently by MariaDB for each table, CONNECT has no global information to decide when it is good to use dynamic indexing. This is why you should use it only on cases where you see that some important join queries take a very long time and only on columns used for joining the table. How to declare an index to be dynamic is by using the Boolean
DYNAM index option. For instance, the query:

```
SELECT d.diag, COUNT(*) cnt FROM diag d, patients p WHERE d.pnb =
p.pnb AND ageyears < 17 AND county = 30 AND drg <> 11 AND d.diag
BETWEEN 4296 AND 9434 GROUP BY d.diag ORDER BY cnt DESC;
```

Such a query joining the diag table to the patients table may last a very long time if the tables are big.
To declare the primary key on the pnb column of the patients table to be dynamic:

```
ALTER TABLE patients DROP PRIMARY KEY;
ALTER TABLE patients ADD PRIMARY KEY (pnb) COMMENT 'DYNAMIC' dynam=1;
```

Note 1: The comment is not mandatory here but useful to see that the index is dynamic if you use the SHOW INDEX command.

Note 2: There is currently no way to just change the DYNAM option without dropping and adding the index. This is unfortunate because it takes time.

Virtual Indexing

It applies only to the virtual tables of type VIR and must be made on a column specifying `SPECIAL=ROWID` or `SPECIAL=ROWNUM`.

This page is licensed: GPLv2

Using CONNECT - Partitioning and Sharding

CONNECT supports the MySQL/MariaDB partition specification. It is done similar to the way MyISAM or InnoDB do by using the PARTITION engine that must be enabled for this to work. This type of partitioning is sometimes referred as “horizontal partitioning”.

Partitioning enables you to distribute portions of individual tables across a file system according to rules which you can set largely as needed. In effect, different portions of a table are stored as separate tables in different locations. The user-selected rule by which the division of data is accomplished is known as a partitioning function, which in MariaDB can be the modulus, simple matching against a set of ranges or value lists, an internal hashing function, or a linear hashing function.

CONNECT takes this notion a step further, by providing two types of partitioning:

1. File partitioning. Each partition is stored in a separate file like in multiple tables.
2. Table partitioning. Each partition is stored in a separate table like in TBL tables.

Partition engine issues

Using partitions sometimes requires creating the tables in an unnatural way to avoid some error due to several partition engine bugs:

1. Engine specific column and index options are not recognized and cause a syntax error when the table is created. The workaround is to create the table in two steps, a `CREATE TABLE` statement followed by an `ALTER TABLE` statement.
2. The connection string, when specified for the table, is lost by the partition engine. The workaround is to specify the connection string in the option_list.
3. MySQL upstream bug #71095. In case of list columns partitioning it sometimes causes a false “impossible where” clause to be raised. This makes a wrong void result returned when it should not be void. There is no workaround but this bug should be hopefully fixed.

The following examples are using the above workaround syntax to address these issues.

File Partitioning

File partitioning applies to file-based CONNECT table types. As with multiple tables, physical data is stored in several files instead of just one. The differences to multiple tables are:

1. Data is distributed amongst the different files following the partition rule.
2. Unlike multiple tables, partitioned tables are not read only.
3. Unlike multiple tables, partitioned tables can be indexable.
4. The file names are generated from the partition names.
5. Query pruning is automatically made by the partition engine.

The table file names are generated differently depending on whether the table is an inward or outward table. For inward tables, for which the file name is not specified, the partition file names are:

```
Data file name: table_name#P#partition_name.table_file_type
Index file name: table_name#P#partition_name.index_file_type
```

For instance for the table:

```
CREATE TABLE t1 (
id INT KEY NOT NULL,
msg VARCHAR(32))
ENGINE=CONNECT TABLE_TYPE=FIX
PARTITION BY RANGE(id) (
PARTITION first VALUES LESS THAN(10),
PARTITION middle VALUES LESS THAN(50),
PARTITION last VALUES LESS THAN(MAXVALUE));
```

CONNECT will generate in the current data directory the files:

```
| t1#P#first.fix
| t1#P#first.fnx
| t1#P#middle.fix
| t1#P#middle.fnx
| t1#P#last.fix
| t1#P#last.fnx
```

This is similar to what the partition engine does for other engines - CONNECT partitioned inward tables behave like other engines partition tables do. Just the data format is different.

Note: If sub-partitioning is used, inward table files and index files are named:

```
| table_name#P#partition_name#SP#subpartition_name.type
| table_name#P#partition_name#SP#subpartition_name.index_type
```

Outward Tables

The real problems occur with outward tables, in particular when they are created from already existing files. The first issue is to make the partition table use the correct existing file names. The second one, only for already existing not void tables, is to be sure the partitioning function match the distribution of the data already existing in the files.

The first issue is addressed by the way data file names are constructed. For instance let us suppose we want to make a table from the fixed formatted files:

```
E:\Data\part1.txt
E:\Data\part2.txt
E:\Data\part3.txt
```

This can be done by creating a table such as:

```
CREATE TABLE t2 (
id INT NOT NULL,
msg VARCHAR(32),
INDEX XID(id))
ENGINE=connect table_type=FIX file_name='E:/Data/part%s.txt'
PARTITION BY RANGE(id) (
PARTITION `1` VALUES LESS THAN(10),
PARTITION `2` VALUES LESS THAN(50),
PARTITION `3` VALUES LESS THAN(MAXVALUE));
```

The rule is that for each partition the matching file name is internally generated by replacing in the given FILE _ NAME option value the “%s” part by the partition name.

If the table was initially void, further inserts will populate it according to the partition function.
However, if the files did exist and contained data, this is your responsibility to determine what partition function actually matches the data distribution in them. This means in particular that partitioning by key or by hash cannot be used (except in exceptional cases) because you have almost no control over what the used algorithm does.

In the example above, there is no problem if the table is initially void, but if it is not, serious problems can be met if the initial distribution does not match the table distribution. Supposing a row in which “id” as the value 12 was initially contained in the part1.txt file, it are seen when selecting the whole table but if you ask:

```
SELECT * FROM t2 WHERE id = 12;
```

The result will have 0 rows. This is because according to the partition function query pruning will only look inside the second partition and will miss the row that is in the wrong partition.

One way to check for wrong distribution if for instance to compare the results from queries such as:

```
SELECT partition_name, table_rows FROM
information_schema.partitions WHERE table_name = 't2';
```

And

```
SELECT CASE WHEN id < 10 THEN 1 WHEN id < 50 THEN 2 ELSE 3 END
AS pn, COUNT(*) FROM part3 GROUP BY pn;
```

If they match, the distribution can be correct although this does not prove it. However, if they do not match, the distribution is surely wrong.

Partitioning on a Special Column

There are some cases where the files of a multiple table do not contain columns that can be used for range or list partitioning. For instance, let's suppose we have a multiple table based on the following files:

```
tmp/boston.txt
tmp/chicago.txt
tmp/atlanta.txt
```

Each of them containing the same kind of data:

```
ID: int
First_name: varchar(16)
Last_name: varchar(30)
Birth: date
Hired: date
Job: char(10)
Salary: double(8,2)
```

A multiple table can be created on them, for instance by:

```
CREATE TABLE mulemp (
id INT NOT NULL,
first_name VARCHAR(16) NOT NULL,
last_name VARCHAR(30) NOT NULL,
birth DATE NOT NULL date_format='DD/MM/YYYY',
hired DATE NOT NULL date_format='DD/MM/YYYY',
job CHAR(10) NOT NULL,
salary DOUBLE(8,2) NOT NULL
) ENGINE=CONNECT table_type=FIX file_name='tmp/*.txt' multiple=1;
```

The issue is that if we want to create a partitioned table on these files, there are no columns to use for defining a partition function. Each city file can have the same kind of column values and there is no way to distinguish them.

However, there is a solution. It is to add to the table a special column that are used by the partition function. For instance, the new table creation can be done by:

```
CREATE TABLE partemp (
id INT NOT NULL,
first_name VARCHAR(16) NOT NULL,
last_name VARCHAR(30) NOT NULL,
birth DATE NOT NULL date_format='DD/MM/YYYY',
hired DATE NOT NULL date_format='DD/MM/YYYY',
job CHAR(16) NOT NULL,
salary DOUBLE(10,2) NOT NULL,
city CHAR(12) DEFAULT 'boston' special=PARTID,
INDEX XID(id)
) ENGINE=CONNECT table_type=FIX file_name='E:/Data/Test/%s.txt';
ALTER TABLE partemp
PARTITION BY LIST COLUMNS(city) (
PARTITION `atlanta` VALUES IN('atlanta'),
PARTITION `boston` VALUES IN('boston'),
PARTITION `chicago` VALUES IN('chicago'));
```

Note 1: we had to do it in two steps because of the column CONNECT options.

Note 2: the special column PARTID returns the name of the partition in which the row is located.

Note 3: here we could have used the FNAME special column instead because the file name is specified as being the partition name.

This may seem rather stupid because it means for instance that a row are in partition boston if it belongs to the partition boston! However, it works because the partition engine doesn't know about special columns and behaves as if the city column was a real column.

What happens if we populate it by?

```
INSERT INTO partemp(id,first_name,last_name,birth,hired,job,salary) VALUES
(1205,'Harry','Cover','1982-10-07','2010-09-21','MANAGEMENT',125000.00);
INSERT INTO partemp VALUES
(1524,'Jim','Beams','1985-06-18','2012-07-25','SALES',52000.00,'chicago'),
(1431,'Johnny','Walker','1988-03-12','2012-08-09','RESEARCH',46521.87,'boston'),
(1864,'Jack','Daniels','1991-12-01','2013-02-16','DEVELOPMENT',63540.50,'atlanta');
```

The value given for the city column (explicitly or by default) are used by the partition engine to decide in which partition to insert the rows. It are ignored by CONNECT (a special column cannot be given a value) but later will return the matching value. For instance:

```
SELECT city, first_name, job FROM partemp WHERE id IN (1524,1431);
```

This query returns:

city	first_name	job
boston	Johnny	RESEARCH
chicago	Jim	SALES

Everything works as if the city column was a real column contained in the table data files.

Partitioning of Zipped Tables

Two cases are currently supported:
If a table is based on several zipped files, portioning is done the standard way as above. This is the *file_name* option specifying the name of the zip files that shall contain the '%s' part used to generate the file names.
If a table is based on only one zip file containing several entries, this is indicated by placing the '%s' part in the entry option value.
Note: If a table is based on several zipped files each containing several entries, only the first case is possible. Using sub-partitioning to make partitions on each entries is not supported yet.

Table Partitioning

With table partitioning, each partition is physically represented by a sub-table. Compared to standard partitioning, this brings the following features:

1. The partitions can be tables driven by different engines. This relieves the current existing limitation of the partition engine.
2. The partitions can be tables driven by engines not currently supporting partitioning.
3. Partition tables can be located on remote servers, enabling table sharding.
4. Like for TBL tables, the columns of the partition table do not necessarily match the columns of the sub-tables.

The way it is done is to create the partition table with a table type referring to other tables, PROXY,MYSQL ODBC or JDBC. Let us see how this is done on a simple example. Supposing we have created the following tables:

```
CREATE TABLE xt1 (
id INT NOT NULL,
msg VARCHAR(32))
ENGINE=myisam;

CREATE TABLE xt2 (
id INT NOT NULL,
msg VARCHAR(32)); /* engine=innoDB */

CREATE TABLE xt3 (
id INT NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=CSV;
```

We can for instance create a partition table using these tables as physical partitions by:

```
CREATE TABLE t3 (
id INT NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=PROXY tabname='xt%s'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `1` VALUES LESS THAN(10),
PARTITION `2` VALUES LESS THAN(50),
PARTITION `3` VALUES LESS THAN(MAXVALUE));
```

Here the name of each partition sub-table are made by replacing the '%s' part of the tabname option value by the partition name. Now if we do:

```
INSERT INTO t3 VALUES
(4, 'four'),(7,'seven'),(10,'ten'),(40,'forty'),
(60,'sixty'),(81,'eighty one'),(72,'seventy two'),
(11,'eleven'),(1,'one'),(35,'thirty five'),(8,'eight');
```

The rows are distributed in the different sub-tables according to the partition function. This can be seen by executing the query:

```
SELECT partition_name, table_rows FROM
information_schema.partitions WHERE table_name = 't3';
```

This query replies:

partition_name	table_rows
1	4
2	4
3	3

Query pruning is of course automatic, for instance:

```
EXPLAIN PARTITIONS SELECT * FROM t3 WHERE id = 81;
```

This query replies:

id	select_type	table	partitions	type	possible_keys	key	key_len	ref	rows	Extra
1	SIMPLE	part5	3	ALL					22	Using where

When executing this select query, only sub-table xt3 are used.

Indexing with Table Partitioning

Using the PROXY table type seems natural. However, in this current version, the issue is that PROXY (and ODBC) tables are not indexable. This is why, if you want the table to be indexed, you must use the MYSQL table type. The CREATE TABLE statement are almost the same:

```
CREATE TABLE t4 (
id INT KEY NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=MYSQL tabname='xt%s'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `1` VALUES LESS THAN(10),
PARTITION `2` VALUES LESS THAN(50),
PARTITION `3` VALUES LESS THAN(MAXVALUE));
```

The column *id* is declared as a key, and the table type is now MYSQL. This makes Sub-tables accessed by calling a MariaDB server as MYSQL tables do. Note that this modifies only the way
CONNECT sub-tables are accessed.

However, indexing just make the partitioned table use “remote indexing” the way FEDERATED tables do. This means that when sending the query to retrieve the table data, a where clause are added to the query. For instance, let’s suppose you ask:

```
SELECT * FROM t4 WHERE id = 7;
```

The query sent to the server are:

```
SELECT `id`, `msg` FROM `xt1` WHERE `id` = 7
```

On a query like this one, it does not change much because the where clause could have been added anyway by the cond_push function, but it does make a difference in case of joins. The main thing to understand is that real indexing is done by the called table and therefore that it should be indexed.

This also means that the `xt1`, `xt2`, and `xt3` table indexes should be made separately because creating the `t2` table as indexed does not make the indexes on the sub-tables.

Sharding with Table Partitioning

Using table partitioning can have one more advantage. Because the sub-tables can address a table located on another server, it is possible to shard a table on separate servers and hardware machines.
This may be required to access as one table data already located on several remote machines, such as servers of a company branches. Or it can be just used to split a huge table for performance reason. For instance, supposing we have created the following tables:

```
CREATE TABLE rt1 (id INT KEY NOT NULL, msg VARCHAR(32))
ENGINE=federated connection='mysql://root@host1/test/sales';

CREATE TABLE rt2 (id INT KEY NOT NULL, msg VARCHAR(32))
ENGINE=federated connection='mysql://root@host2/test/sales';

CREATE TABLE rt3 (id INT KEY NOT NULL, msg VARCHAR(32))
ENGINE=federated connection='mysql://root@host3/test/sales';
```

Creating the partition table accessing all these are almost like what we did with the t4 table:

```
CREATE TABLE t5 (
id INT KEY NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=MYSQL tabname='rt%s'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `1` VALUES LESS THAN(10),
PARTITION `2` VALUES LESS THAN(50),
PARTITION `3` VALUES LESS THAN(MAXVALUE));
```

The only difference is the tabname option now referring to the rt1, rt2, and rt3 tables. However, even if it works, this is not the best way to do it. This is because accessing a table via the MySQL API is done twice per table. Once by CONNECT to access the FEDERATED table on the local server, then a second time by FEDERATED engine to access the remote table.

The CONNECT MYSQL table type being used anyway, you'd rather use it to directly access the remote tables. Indeed, the partition names can also be used to modify the connection URL's. For instance, in the case shown above, the partition table can be created as:

```
CREATE TABLE t6 (
id INT KEY NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=MYSQL
option_list='connect=mysql://root@host%s/test/sales'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `1` VALUES LESS THAN(10),
PARTITION `2` VALUES LESS THAN(50),
PARTITION `3` VALUES LESS THAN(MAXVALUE));
```

Several things can be noted here:

1. As we have seen before, the partition engine currently loses the connection string. This is why it was specified as "connect" in the option list.
2. For each partition sub-tables, the "%s" part of the connection string has been replaced by the partition name.
3. It is not needed anymore to define the rt1, rt2, and rt3 tables (even it does not harm) and the FEDERATED engine is no more used to access the remote tables.

This is a simple case where the connection string is almost the same for all the sub-tables. But what if the sub-tables are accessed by very different connection strings? For instance:

```
For rt1: connection='mysql://root:tinono@127.0.0.1:3307/test/xt1'
For rt2: connection='mysql://foo:foopass@denver/dbemp/xt2'
For rt3: connection='mysql://root@huston :5505/test/tabx'
```

There are two solutions. The first one is to use the parts of the connection string to differentiate as partition names:

```
CREATE TABLE t7 (
id INT KEY NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=MYSQL
option_list='connect=mysql://%s'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `root:tinono@127.0.0.1:3307/test/xt1` VALUES LESS THAN(10),
PARTITION `foo:foopass@denver/dbemp/xt2` VALUES LESS THAN(50),
PARTITION `root@huston :5505/test/tabx` VALUES LESS THAN(MAXVALUE));
```

The second one, allowing avoiding too complicated partition names, is to create federated servers to access the remote tables (if they do not already exist, else just use them). For instance the first one could be:

```
CREATE SERVER `server_one` FOREIGN DATA WRAPPER 'mysql'
OPTIONS
(HOST '127.0.0.1',
DATABASE 'test',
USER 'root',
PASSWORD 'tinono',
PORT 3307);
```

Similarly, “server_two” and “server_three” would be created and the final partition table would be created as:

```
CREATE TABLE t8 (
id INT KEY NOT NULL,
msg VARCHAR(32))
ENGINE=connect table_type=MYSQL
option_list='connect=server_%s'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `one/xt1` VALUES LESS THAN(10),
PARTITION `two/xt2` VALUES LESS THAN(50),
PARTITION `three/tabx` VALUES LESS THAN(MAXVALUE));
```

It would be even simpler if all remote tables had the same name on the remote databases, for instance if they all were named xt1, the connection string could be set as “server_%s/xt1” and the partition names would be just “one”, “two”, and “three”.

Sharding on a Special Column

The technique we have seen above with file partitioning is also available with table partitioning.
Companies willing to use as one table data sharded on the company branch servers can, as we have seen, add to the table create definition a special column. For instance:

```
CREATE TABLE t9 (
id INT NOT NULL,
msg VARCHAR(32),
branch CHAR(16) DEFAULT 'main' special=PARTID,
INDEX XID(id))
ENGINE=connect table_type=MYSQL
option_list='connect=server_%s/sales'
PARTITION BY RANGE COLUMNS(id) (
PARTITION `main` VALUES IN('main'),
PARTITION `east` VALUES IN('east'),
PARTITION `west` VALUES IN('west'));
```

This example assumes that federated servers had been created named “server_main”, “server_east” and “server_west” and that all remote tables are named “sales”. Note also that in this example, the column id is no more a key.

Current Partition Limitations

Because the partition engine was written before some other engines were added to MariaDB, the way it works is sometime incompatible with these engines, in particular with CONNECT.

Update Statement

With the sample tables above, you can do update statements such as:

```
UPDATE t2 SET msg = 'quatre' WHERE id = 4;
```

It works perfectly and is accepted by CONNECT. However, let us consider the statement:

```
UPDATE t2 SET id = 41 WHERE msg = 'four';
```

This statement is not accepted by CONNECT. The reason is that the column id being part of the partition function, changing its value may require the modified row to be moved to another partition.
The way it is done by the partition engine is to delete the old row and to re-insert the new modified one. However, this is done in a way that is not currently compatible with CONNECT (remember that
CONNECT supports UPDATE in a specific way, in particular for the table type MYSQL)
This limitation could be temporary. Meanwhile the workaround is to manually do what is done above,

Deleting the row to modify and inserting the modified row:

```
DELETE FROM t2 WHERE id = 4;
INSERT INTO t2 VALUES(41, 'four');
```

Alter Table Statement

For all CONNECT outward tables, the `ALTER TABLE` statement does not make any change in the table data. This is why `ALTER TABLE` should not be used; in particular to modify the partition definition, except of course to correct a wrong definition. Note that using `ALTER TABLE` to create a partition table in two steps because column options would be lost is valid as it applies to a table that is not yet partitioned.

As we have seen, it is also safe to use it to create or drop indexes. Otherwise, a simple rule of thumb is to avoid altering a table definition and better drop and re-create a table whose definition must be modified. Just remember that for outward CONNECT tables, dropping a table does not erase the data and that creating it does not modify existing data.

Rowid Special Column

Each partition being handled separately as one table, the `ROWID` special column returns the rank of the row in its partition, not in the whole table. This means that for partition tables `ROWID` and `ROWNUM` are equivalent.

This page is licensed: CC BY-SA / Gnu FDL

Using CONNECT - Virtual and Special Columns

CONNECT supports MariaDB virtual and persistent columns. It is also possible to declare a column as being a CONNECT special column. Let us see on an example how this can be done. The boys table we have seen previously can be recreated as:

```
CREATE TABLE boys (
  linenum INT(6) NOT NULL DEFAULT 0 special=ROWID,
  name CHAR(12) NOT NULL,
  city CHAR(12) NOT NULL,
  birth DATE NOT NULL date_format='DD/MM/YYYY',
  hired DATE NOT NULL date_format='DD/MM/YYYY' flag=36,
  agehired INT(3) AS (floor(datediff(hired,birth)/365.25))
  virtual,
  fn CHAR(100) NOT NULL DEFAULT '' special=FILEID)
ENGINE=CONNECT table_type=FIX file_name='boys.txt' mapped=YES lrecl=47;
```

We have defined two CONNECT special columns. You can give them any name; it is the field `SPECIAL` option that specifies the special column functional name.

Note: the default values specified for the special columns do not mean anything. They are specified just to prevent getting warning messages when inserting new rows.

For the definition of the *agehired* virtual column, no CONNECT options can be specified as it has no offset or length, not being stored in the file.

The command:

```
SELECT * FROM boys WHERE city = 'boston';
```

will return:

linenum	name	city	birth	hired	agehired	fn
1	John	Boston	1986-01-25	2010-06-02	24	d:\mariadb\sql\data\boys.txt
2	Henry	Boston	1987-06-07	2008-04-01	20	d:\mariadb\sql\data\boys.txt
6	Bill	Boston	1986-09-11	2008-02-10	21	d:\mariadb\sql\data\boys.txt

Existing special columns are listed in the following table:

Special Name	Type	Description of the column value
ROWID	Integer	The row ordinal number in the table. This is not quite equivalent to a virtual column with an auto increment of 1 because rows are renumbered when deleting rows.
ROWNUM	Integer	The row ordinal number in the file. This is different from ROWID for multiple tables, TBL/XCOL/OCCUR/PIVOT tables, XML tables with a multiple column, and for DBF tables where ROWNUM includes soft deleted rows.
FILEID FDISK FPATH FNAME FTYPE	String	FILEID returns the full name of the file this row belongs to. Useful in particular for multiple tables represented by several files. The other special columns can be used to retrieve only one part of the full name.
TABID	String	The name of the table this row belongs to. Useful for TBL tables.
PARTID	String	The name of the partition this row belongs to. Specific to partitioned tables.
SERVID	String	The name of the federated server or server host used by a MYSQL table. “ODBC” for an ODBC table, “JDBC” for a JDBC table and “Current” for all other tables.

Note: CONNECT does not currently support auto incremented columns. However, a `ROWID` special column will do the job of a column auto incremented by 1.

This page is licensed: GPLv2

Installing CONNECT

The `CONNECT` storage engine enables MariaDB to access external local or remote data (MED). This is done by defining tables based on different data types, in particular files in various formats, data extracted from other DBMS or products (such as Excel or MongoDB) via ODBC or JDBC, or data retrieved from the environment (for example DIR, WMI, and MAC tables).

This storage engine supports table partitioning, MariaDB virtual columns and permits defining special columns such as ROWID, FILEID, and SERVID.

The storage engine must be installed before it can be used.

Installing the Plugin's Package

The `CONNECT` storage engine's shared library is included in MariaDB packages as the `ha_connect.so` or `ha_connect.so` shared library on systems where it can be built.

Installing on Linux

The `CONNECT` storage engine is included in binary tarballs on Linux.

Installing with a Package Manager

The `CONNECT` storage engine can also be installed via a package manager on Linux. In order to do so, your system needs to be configured to install from one of the MariaDB repositories.

You can configure your package manager to install it from MariaDB Corporation's MariaDB Package Repository by using the MariaDB Package Repository setup script.

You can also configure your package manager to install it from MariaDB Foundation's MariaDB Repository by using the MariaDB Repository Configuration Tool.

Installing with yum/dnf

On RHEL, CentOS, Fedora, and other similar Linux distributions, it is highly recommended to install the relevant RPM package from MariaDB's repository using yum or dnf. Starting with RHEL 8 and Fedora 22, `yum` has been replaced by `dnf`, which is the next major version of `yum`. However, `yum` commands still work on many systems that use `dnf`:

```
sudo yum install MariaDB-connect-engine
```

Installing with apt-get

On Debian, Ubuntu, and other similar Linux distributions, it is highly recommended to install the relevant DEB package from MariaDB's repository using apt-get:

```
sudo apt-get install mariadb-plugin-connect
```

Installing with zypper

On SLES, OpenSUSE, and other similar Linux distributions, it is highly recommended to install the relevant RPM package from MariaDB's repository using zypper:

```
sudo zypper install MariaDB-connect-engine
```

Installing the Plugin

Once the shared library is in place, the plugin is not actually installed by MariaDB by default. There are two methods that can be used to install the plugin with MariaDB.

The first method can be used to install the plugin without restarting the server. You can install the plugin dynamically by executing INSTALL SONAME or INSTALL PLUGIN:

```
INSTALL SONAME 'ha_connect';
```

The second method can be used to tell the server to load the plugin when it starts up. The plugin can be installed this way by providing the –plugin-load or the –plugin-load-add options. This can be specified as a command-line argument to mysqld or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
plugin_load_add = ha_connect
```

Uninstalling the Plugin

You can uninstall the plugin dynamically by executing UNINSTALL SONAME or UNINSTALL PLUGIN:

```
UNINSTALL SONAME 'ha_connect';
```

If you installed the plugin by providing the –plugin-load or the –plugin-load-add options in a relevant server option group in an option file, then those options should be removed to prevent the plugin from being loaded the next time the server is restarted.

Installing Dependencies

The `CONNECT` storage engine has some external dependencies.

Installing unixODBC

The `CONNECT` storage engine requires an ODBC library. On Unix-like systems, that usually means installing unixODBC. On some systems, this is installed as the `unixODBC` package:

```
sudo yum install unixODBC
```

On other systems, this is installed as the `libodbc1` package:

```
sudo apt-get install libodbc1
```

If you do not have the ODBC library installed, then you may get an error about a missing library when you attempt to install the plugin:

```
INSTALL SONAME 'ha_connect';
ERROR 1126 (HY000): Can't open shared library
'/home/ian/MariaDB_Downloads/10.1.17/lib/plugin/ha_connect.so'
  (errno: 2, libodbc.so.1: cannot open shared object file: No such file or directory)
```

CONNECT Create Table Options

Create Table statements for “CONNECT” tables are standard MariaDB create statements specifying `engine=CONNECT` . There are a few additional table and column options specific to CONNECT.

Table Options

Table Option	Type	Description
AVG_ROW_LENGTH	Integer	Can be specified to help CONNECT estimate the size of a variable record table length.
BLOCK_SIZE	Integer	The number of rows each block of a FIX, BIN, DBF, or VEC table contains. For an ODBC table this is the RowSet size option. For a JDBC table this is the fetch size.
CATFUNC	String	The catalog function used by a catalog table.
COLIST	String	The column list of OCCUR tables or $project of MONGO tables.
COMPRESS	Number	1 or 2 if the data file is g-zip compressed. Defaults to 0. Before CONNECT 1.05.0001, this was boolean, and true if the data file is compressed.
CONNECTION	String	Specifies the connection of an ODBC, JDBC or MYSQL table.
DATA_CHARSET	String	The character set used in the external file or data source.
DBNAME	String	The target database for ODBC, JDBC, MYSQL, catalog, and PROXY based tables. The database concept is sometimes known as a schema.
ENGINE	String	Must be specified as CONNECT.
ENDING	Integer	End of line length. Defaults to 1 for Unix/Linux and 2 for Windows.
FILE_NAME	String	The file (path) name for all table types based on files. Can be absolute or relative to the current data directory. If not specified, this is an Inward table and a default value is used.
FILTER	String	To filter an external table. Currently MONGO tables only.
HEADER	Integer	Applies to CSV, VEC, and HTML files. Its meaning depends on the table type.
HTTP	String	The HTTP of the client of REST queries. From Connect 1.06.0010.
HUGE	Boolean	To specify that a table file can be larger than 2GB. For a MYSQL table, prevents the result set from being stored in memory.
LRECL	Integer	The file record size (often calculated by default).
MAPPED	Boolean	Specifies whether file mapping is used to handle the table file.
MODULE	String	The (path) name of the DLL or shared lib implementing the access of a non-standard (OEM) table type.
MULTIPLE	Integer	Used to specify multiple file tables.
OPTION_LIST	String	Used to specify all other options not yet directly defined.
QCHAR	String	Specifies the character used for quoting some fields of a CSV table or the identifiers of an ODBC/JDBC tables.
QUOTED	Integer	The level of quoting used in CSV table files.

Table Option	Type	Description
READONLY	Boolean	True if the data file must not be modified or erased.
SEP_CHAR	String	Specifies the field separator character of a CSV or XCOL table. Also, used to specify the Jpath separator for JSON tables.
SEPINDEX	Boolean	When true, indexes are saved in separate files.
SPLIT	Boolean	True for a VEC table when all columns are in separate files.
SRCDEF	String	The source definition of a table retrieved via ODBC, JDBC or the MySQL API or used by a PIVOT table.
SUBTYPE	String	The subtype of an OEM table type.
TABLE_LIST	String	The comma separated list of TBL table sub-tables.
TABLE_TYPE	String	The external table type: DOS, FIX, BIN, CSV, FMT, XML, JSON, INI, DBF, VEC, ODBC, JDBC, MYSQL, TBL, PROXY, XCOL, OCCUR, PIVOT, ZIP, VIR, DIR, WMI, MAC, and OEM. Defaults to DOS, MYSQL, or PROXY depending on what options are used.
TABNAME	String	The target table or node for ODBC, JDBC, MYSQL, PROXY, or catalog tables; or the top node name for XML tables.
URI	String	The URI of a REST request.. From Connect 1.06.0010.
XFILE_NAME	String	The file (path) base name for table index files. Can be absolute or relative to the data directory. Defaults to the file name.
ZIPPED	Boolean	True if the table file(s) is/are zipped in one or several zip files.

All integers in the above table are unsigned big integers.

Because CONNECT handles many table types; many table type specific options are not in the above list and must be entered using the `OPTION_LIST` option. The syntax to use is:

```
... option_list='opname1=opvalue1,opname2=opvalue2...'
```

Be aware that until Connect 1.5.5, no blanks should be inserted before or after the '`=`' and '`,`' characters. The option name is all that is between the start of the string or the last '`,`' character and the next '`=`' character, and the option value is all that is between this '`=`' character and the next '`,`' or end of string. For instance:

```
option_list='name=TABLE,coltype=HTML,attribute=border=1;cellpadding=5,headattr=bgcolor=yellow';
```

This defines four options, '`name`', '`coltype`', '`attribute`', and '`headattr`'; with values '`TABLE`', '`HTML`', '`border=1;cellpadding=5`', and '`bgcolor=yellow`', respectively. The only restriction is that values cannot contain commas, but they can contain equal signs.

Column Options

Column Option	Type	Description
DATE_FORMAT	String	The format indicating how a date is stored in the file.
DISTRIB	Enum	"scattered", "clustered", "sorted" (ascending).
FIELD_FORMAT	String	The column format for some table types.

Column Option	Type	Description
FIELD_LENGTH	Integer	Set the internal field length for DATE columns.
FLAG	Integer	An integer value whose meaning depends on the table type.
JPATH	String	The Json path of JSON table columns.
MAX_DIST	Integer	Maximum number of distinct values in this column.
SPECIAL	String	The name of the SPECIAL column that set this column value.
XPATH	String	The XML path of XML table columns.

- The `MAX_DIST` and `DISTRIB` column options are used for block indexing.
- All integers in the above table are unsigned big integers.
- JPATH and XPATH were added to make CREATE TABLE statements more readable, but they do the same thing as FIELD_FORMAT and any of them can be used with the same result.

Index Options

Index Option	Type	Description
DYNAM	Boolean	Set the index as “dynamic”.
MAPPED	Boolean	Use index file mapping.

Note 1: Creating a CONNECT table based on file does not erase or create the file if the file name is specified in the `CREATE TABLE` statement (“outward” table). If the file does not exist, it are populated by subsequent `INSERT` or `LOAD` statements or by the “AS select statement” of the CREATE TABLE statement. Unlike the CSV engine, CONNECT easily permits the creation of tables based on already existing files, for instance files made by other applications. However, if the file name is not specified, a file with a name defaulting to `tablename.tabletype` are created in the data directory (“inward” table).

Note 2: Dropping a CONNECT table is done with a standard `DROP` statement. For outward tables, this drops only the CONNECT table definition but does not erase the corresponding data file and index files. Use `DELETE` or `TRUNCATE` to do so. This is contrary to data and index files of inward tables are erased on `DROP` like for other MariaDB engines.

This page is licensed: GPLv2

CONNECT Data Types

Many data types make no or little sense when applied to plain files. This why CONNECT supports only a restricted set of data types. However, ODBC, JDBC or MYSQL source tables may contain data types not supported by CONNECT. In this case, CONNECT makes an automatic conversion to a similar supported type when it is possible.

The data types currently supported by CONNECT are:

Type name	Description	Used for
TYPE_STRING	Zero ended string	char, varchar, text
TYPE_INT	4 bytes integer	int, mediumint, integer
TYPE_SHORT	2 bytes integer	smallint
TYPE_TINY	1 byte integer	tinyint
TYPE_BIGINT	8 bytes integer	bigint, longlong
TYPE_DOUBLE	8 bytes floating point	double, float, real
TYPE_DECIM	Numeric value	decimal, numeric, number
TYPE_DATE	4 bytes integer	date, datetime, time, timestamp, year

TYPE_STRING

This type corresponds to what is generally known as CHAR or VARCHAR by database users, or as strings by programmers. Columns containing characters have a maximum length but the character string is of fixed or variable length depending on the file format.

The `DATA_CHARSET` option must be used to specify the character set used in the data source or file. Note that, unlike usually with MariaDB, when a multi-byte character set is used, the column size represents the number of bytes the column value can contain, not the number of characters.

TYPE_INT

The INTEGER type contains signed integer numeric 4-byte values (the *int* of the C language) ranging from `-2,147,483,648` to `2,147,483,647` for signed type and `0` to `4,294,967,295` for unsigned type.

TYPE_SHORT

The `SHORT` data type contains signed integer numeric 2-byte values (the *short integer* of the C language) ranging from `-32,768` to `32,767` for signed type and `0` to `65,535` for unsigned type.

TYPE_TINY

The `TINY` data type contains integer numeric 1-byte values (the *char* of the C language) ranging from `-128` to `127` for signed type and `0` to `255` for unsigned type. For some table types, TYPE_TINY is used to represent Boolean values (0 is false, anything else is true).

TYPE_BIGINT

The BIGINT data type contains signed integer 8-byte values (the *long long* of the C language) ranging from `-9,223,372,036,854,775,808` to `9,223,372,036,854,775,807` for signed type and from `0` to `18,446,744,073,709,551,615` for unsigned type.

Inside tables, the coding of all integer values depends on the table type. In tables represented by text files, the number is written in characters, while in tables represented by binary files (`BIN` or `VEC`) the number is directly stored in the binary representation corresponding to the platform.

The *length* (or *precision*) specification corresponds to the length of the table field in which the value is stored for text files only. It is used to set the output field length for all table types.

TYPE_DOUBLE

The `DOUBLE` data type corresponds to the C language double type, a floating-point double precision value coded with 8 bytes. Like for integers, the internal coding in tables depends on the table type, characters for text files, and platform binary representation for binary files.

The *length* specification corresponds to the length of the table field in which the value is stored for text files only. The *scale* (was_precision_) is the number of decimal digits written into text files. For binary table types (BIN and VEC) this does not apply. The *length* and_scale_ specifications are used to set the output field length and number of decimals for all types of tables.

TYPE_DECIM

The `DECIMAL` data type corresponds to what MariaDB or ODBC data sources call `NUMBER` , `NUMERIC` , or DECIMAL: a numeric value with a maximum number of digits (the precision) some of them eventually being decimal digits (the scale). The internal coding in `CONNECT` is a character representation of the number. For instance:

```
colname DECIMAL(14,6)
```

This defines a column *colname* as a number having a *precision* of 14 and a *scale* of 6. Supposing it is populated by:

```
INSERT INTO xxx VALUES (-2658.74);
```

The internal representation of it are the character string `-2658.740000`. The way it is stored in a file table depends on the table type. The *length* field specification corresponds to the length of the table field in which the value is stored and is calculated by CONNECT from the_precision_ and the *scale* values. This length is *precision* plus 1 if_scale_ is not 0 (for the decimal point) plus 1 if this column is not unsigned (for the eventual minus sign). In fix formatted tables the number is right justified in the field of width *length*, for variable formatted tables, such as CSV, the field is the representing character string.

Because this type is mainly used by CONNECT to handle numeric or decimal fields of ODBC, JDBC and MySQL table types, CONNECT does not provide decimal calculations or comparison by itself. This is why decimal columns of CONNECT tables cannot be indexed.

DATE Data Type

Internally, date/time values are stored by CONNECT as a signed 4-byte integer. The value 0 corresponds to 01 January 1970 12:00:00 am coordinated universal time (UTC). All other date/time values are represented by the number of seconds elapsed since or before midnight (00:00:00), 1 January 1970, to that date/time value. Date/time values before midnight 1 January 1970 are represented by a negative number of seconds.

`CONNECT` handles dates from **13 December 1901, 20:45:52** to**18 January 2038, 19:14:07**.

Although date and time information can be represented in both CHAR and INTEGER data types, the DATE data type has special associated properties. For each DATE value, CONNECT can store all or only some of the following information: century, year, month, day, hour, minute, and second.

Date Format in Text Tables

Internally, date/time values are handled as a signed 4-byte integer. But in text tables (type DOS, FIX, CSV, FMT, and DBF) dates are most of the time stored as a formatted character string (although they also can be stored as a numeric string representing their internal value). Because there are infinite ways to format a date, the format to use for decoding dates, as well as the field length in the file, must be associated to date columns (except when they are stored as the internal numeric value).

Note that this associated format is used only to describe the way the temporal value is stored internally. This format is used both for output to decode the date in a SELECT statement as well as for input to encode the date in INSERT or UPDATE statements. However, what is kept in this value depends on the data type used in the column definition (all the MariaDB temporal values can be specified). When creating a table, the format is associated to a date column using the DATE_FORMAT option in the column definition, for instance:

```
CREATE TABLE birthday (
  Name VARCHAR(17),
  Bday DATE field_length=10 date_format='MM/DD/YYYY',
  Btime TIME field_length=8 date_format='hh:mm tt')
engine=CONNECT table_type=CSV;

INSERT INTO birthday VALUES ('Charlie','2012-11-12','15:30:00');

SELECT * FROM birthday;
```

The `SELECT` query returns:

Name	Bday	Btime
Charlie	2012-11-12	15:30:00

The values of the INSERT statement must be specified using the standard MariaDB syntax and these values are displayed as MariaDB temporal values. Sure enough, the column formats apply only to the way these values are represented inside the CSV files. Here, the inserted record are:

```
Charlie,11/12/2012,03:30 PM
```

Note: The field_length option exists because the MariaDB syntax does not allow specifying the field length between parentheses for temporal column types. If not specified, the field length is calculated from the date format (sometimes as a max value) or made equal to the default length value if there is no date format. In the above example it could have been removed as the calculated values are the ones specified. However, if the table type would have been DOS or FIX, these values could be adjusted to fit the actual field length within the file.

A `CONNECT` format string consists of a series of elements that represent a particular piece of information and define its format. The elements are recognized in the order they appear in the format string. Date and time format elements are replaced by the actual date and time as they appear in the source string. They are defined by the following groups of characters:

Element	Description
YY	The last two digits of the year (that is, 1996 would be coded as “96”).
YYYY	The full year (that is, 1996 could be entered as “96” but displayed as “1996”).
MM	The one or two-digit month number.
MMM	The three-character month abbreviation.
MMMM	The full month name.
DD	The one or two-digit month day.
DDD	The three-character weekday abbreviation.
DDDD	The full weekday name.
hh	The one or two-digit hour in 12-hour or 24-hour format.
mm	The one or two-digit minute.
ss	The one or two-digit second.
t	The one-letter AM/PM abbreviation (that is, AM is entered as “A”).
tt	The two-letter AM/PM abbreviation (that is, AM is entered as “AM”).

Usage Notes

- To match the source string, you can add body text to the format string, enclosing it in single quotes or double quotes if it would be ambiguous. Punctuation marks do not need to be quoted.
- The hour information is regarded as 12-hour format if a “t” or “tt” element follows the “hh” element in the format or as 24-hour format otherwise.
- The “MM”, “DD”, “hh”, “mm”, “ss” elements can be specified with one or two letters (e.g. “MM” or “M”) making no difference on input, but placing a leading zero to one-digit values on output [1] for two-letter elements.
- If the format contains elements DDD or DDDD, the day of week name is skipped on input and ignored to calculate the internal date value. On output, the correct day of week name is generated and displayed.
- Temporal values are always stored as numeric in BIN and VEC tables.

Handling dates that are out of the range of supported CONNECT dates

If you want to make a table containing, for instance, historical dates not being convertible into CONNECT dates, make your column `CHAR` or `VARCHAR` and store the dates in the MariaDB format. All date functions applied to these

strings will convert them to MariaDB dates and will work as if they were real dates. Of course they must be inserted and are displayed using the MariaDB format.

NULL Handling

`CONNECT` handles null values for data sources able to produce nulls. Currently this concerns mainly the ODBC, JDBC, MONGO, MYSQL, XML, JSON and INI table types. For INI, JSON, MONGO or XML types, null values are returned when the key is missing in the section (INI) or when the corresponding node does not exist in a row (XML, JSON, MONGO).

For other file tables, the issue is to define what a null value is. In a numeric column, 0 can sometimes be a valid value but, in some other cases, it can make no sense. The same for character columns; is a blank field a valid value or not?

A special case is DATE columns with a DATE _FORMAT specified. Any value not matching the format can be regarded as NULL.

`CONNECT` leaves the decision to you. When declaring a column in the CREATE TABLE statement, if it is declared NOT NULL, blank or zero values are considered as valid values. Otherwise they are considered as NULL values. In all cases, nulls are replaced on insert or update by pseudo null values, a zero-length character string for text types or a zero value for numeric types. Once converted to pseudo null values, they are recognized as NULL only for columns declared as nullable.

For instance:

```
CREATE TABLE t1 (a INT, b CHAR(10)) ENGINE=CONNECT;
INSERT INTO t1 VALUES (0,'zero'),(1,'one'),(2,'two'),(NULL,'???');
SELECT * FROM t1 WHERE a IS NULL;
```

The select query replies:

a	b
NULL	zero
NULL	???

Sure enough, the value 0 entered on the first row is regarded as NULL for a nullable column. However, if we execute the query:

```
SELECT * FROM t1 WHERE a = 0;
```

This will return no line because a NULL is not equal to 0 in an SQL where clause.

Now let us see what happens with not null columns:

```
CREATE TABLE t1 (a INT NOT NULL, b CHAR(10) NOT NULL) ENGINE=CONNECT;
INSERT INTO t1 VALUES (0,'zero'),(1,'one'),(2,'two'),(NULL,'???');
```

The insert statement will produce a warning saying:

Level	Code	Message
Warning	1048	Column 'a' cannot be null

It is replaced by a pseudo null `0` on the fourth row. Let us see the result:

```
SELECT * FROM t1 WHERE a IS NULL;
SELECT * FROM t1 WHERE a = 0;
```

The first query returns no rows, 0 are valid values and not NULL. The second query replies:

a	b
0	zero
0	???

It shows that the NULL inserted value was replaced by a valid 0 value.

Unsigned Numeric Types

They are supported by CONNECT since version 1.01.0010 for fixed numeric types (TINY, SHORT, INTEGER, and BITINT).

Data Type Conversion

`CONNECT` is able to convert data from one type to another in most cases. These conversions are done without warning even when this leads to truncation or loss of precision. This is true, in particular, for tables of type ODBC, JDBC, MYSQL and PROXY (via MySQL) because the source table may contain some data types not supported by `CONNECT`. They are converted when possible to `CONNECT` types.

When converted, MariaDB types are converted as:

MariaDB Types	CONNECT Type	Remark
integer, medium integer	TYPE_INT	4 byte integer
small integer	TYPE_SHORT	2 byte integer
tiny integer	TYPE_TINY	1 byte integer
char, varchar	TYPE_STRING	Same length
double, float, real	TYPE_DOUBLE	8 byte floating point
decimal, numeric	TYPE_DECIM	Length depends on precision and scale
all date related types	TYPE_DATE	Date format can be set accordingly
bigint, longlong	TYPE_BIGINT	8 byte integer
enum, set	TYPE_STRING	Numeric value not accessible
All text types	TYPE_STRING TYPE_ERROR	Depending on the value of the connect_type_conv system variable value.
Other types	TYPE_ERROR	Not supported, no conversion provided.

For ENUM, the length of the column is the length of the longest value of the enumeration. For SET the length is enough to contain all the set values concatenated with comma separator.

In the case of TEXT columns, the handling depends on the values given to the connect_type_conv and connect_conv_size system variables.

Note: BLOB is currently not converted by default until a TYPE_BIN type is added to CONNECT. However, the FORCE option (from Connect 1.06.006) can be specified for blob columns containing text and the SKIP option also applies to ODBC BLOB columns.

ODBC SQL types are converted as:

SQL Types	Connect Type	Remark
SQL_CHAR, SQL_VARCHAR	TYPE_STRING	
SQL_LONGVARCHAR	TYPE_STRING	len = min(abs(len), connect_conv_size) If the column is generated by discovery (columns not specified) its length is connect_conv_size.

SQL Types	Connect Type	Remark
SQL_NUMERIC, SQL_DECIMAL	TYPE_DECIM	
SQL_INTEGER	TYPE_INT	
SQL_SMALLINT	TYPE_SHORT	
SQL_TINYINT, SQL_BIT	TYPE_TINY	
SQL_FLOAT, SQL_REAL, SQL_DOUBLE	TYPE_DOUBLE	
SQL_DATETIME	TYPE_DATE	len = 10
SQL_INTERVAL	TYPE_STRING	len = 8 + ((scale) ? (scale+1) : 0)
SQL_TIMESTAMP	TYPE_DATE	len = 19 + ((scale) ? (scale +1) : 0)
SQL_BIGINT	TYPE_BIGINT	
SQL_GUID	TYPE_STRING	llen=36
SQL_BINARY, SQL_VARBINARY, SQL_LONG-VARBINARY	TYPE_STRING	len = min(abs(len), connect_conv_size) Only if the value of connect_type_conv is force. The column should use the binary charset.
Other types	TYPE_ERROR	Not supported.

JDBC SQL types are converted as:

JDBC Types	Connect Type	Remark
(N)CHAR, (N)VARCHAR	TYPE_STRING	
LONG(N)VARCHAR	TYPE_STRING	len = min(abs(len), connect_conv_size) If the column is generated by discovery (columns not specified), its length is connect_conv_size
NUMERIC, DECIMAL, VARBINARY	TYPE_DECIM	
INTEGER	TYPE_INT	
SMALLINT	TYPE_SHORT	
TINYINT, BIT	TYPE_TINY	
FLOAT, REAL, DOUBLE	TYPE_DOUBLE	
DATE	TYPE_DATE	len = 10
TIME	TYPE_DATE	len = 8 + ((scale) ? (scale+1) : 0)
TIMESTAMP	TYPE_DATE	len = 19 + ((scale) ? (scale +1) : 0)
BIGINT	TYPE_BIGINT	
UUID (specific to PostgreSQL)	TYPE_STRINGTYPE_ERROR	len=36If connect_type_conv=NO
Other types	TYPE_ERROR	Not supported.

Note: The connect_type_conv SKIP option also applies to ODBC and JDBC tables.

1. ↑ Here input and output are used to specify respectively decoding the date to get its numeric value from the data file and encoding a date to write it in the table file. Input is performed within SELECT queries; output is performed in UPDATE or INSERT queries.

CONNECT Table Types Overview

CONNECT can handle very many table formats; it is indeed one of its main features. The Type option specifies the type and format of the table. The Type options available values and their descriptions are listed in the following table:

Type	Description
BIN	Binary file with numeric values in platform representation, also with columns at fixed offset within records and fixed record length.

Type	Description
BSON	(Temporary) JSON table handled by the new JSON handling.
CSV *$	“Comma Separated Values” file in which each variable length record contains column values separated by a specific character (defaulting to the comma)
DBF *	File having the dBASE format.
DOS	The table is contained in one or several files. The file format can be refined by some other options of the command or more often using a specific type as many of those described below. Otherwise, it is a flat text file where columns are placed at a fixed offset within each record, the last column being of variable length.
DIR	Virtual table that returns a file list like the Unix ls or DOS dir command.
FIX	Text file arranged like DOS but with fixed length records.
FMT	File in which each record contains the column values in a non-standard format (the same for each record) This format is specified in the column definition.
INI	File having the format of the initialization or configuration files used by many applications.
JDBC*	Table accessed via a JDBC driver.
JSON*$	File having the JSON format.
MAC	Virtual table returning information about the machine and network cards (Windows only).
MONGO *	Table accessed via the MongoDB C Driver API.
MYSQL*	Table accessed using the MySQL API like the FEDERATED engine.
OCCUR*	A table based on another table existing on the current server, several columns of the object table containing values that can be grouped in only one column.
ODBC*	Table extracted from an application accessible via ODBC or unixODBC. For example from another DBMS or from an Excel spreadsheet.
OEM *	Table of any other formats not directly handled by CONNECT but whose access is implemented by an external FDW (foreign data wrapper) written in C++ (as a DLL or Shared Library).
PIVOT*	Used to “pivot” the display of an existing table or view.
PROXY*	A table based on another table existing on the current server.
TBL*	Accessing a collection of tables as one table (like the MERGE engine does for MyIsam tables)
VEC	Binary file organized in vectors, in which column values are grouped consecutively, either split in separate files or in a unique file.
VIR*	Virtual table containing only special and virtual columns.
WMI *	Windows Management Instrumentation table displaying information coming from a WMI provider. This type enables to get in tabular format all sorts of information about the machine hardware and operating system (Windows only).
XCOL*	A table based on another table existing on the current server with one of its columns containing comma separated values.
XML *$	File having the XML or HTML format.
ZIP	Table giving information about the contents of a zip file.

Catalog Tables

For all table types marked with a '*' in the table above, CONNECT is able to analyze the data source to retrieve the column definition. This can be used to define a "catalog" table that display the column description of the source, or to create a table without specifying the column definition that are automatically constructed by CONNECT when creating the table.

When marked with a '$' the file can be the result returned by a REST query.

This page is licensed: GPLv2

CONNECT BIN Table Type

Overview

A table of type BIN is physically a binary file in which each row is a logical record of fixed length[1]. Within a record, column fields are of a fixed offset and length as with FIX tables. Specific to BIN tables is that numerical values are internally encoded using native platform representation, so no conversion is needed to handle numerical values in expressions.

It is not required that the lines of a BIN file be separated by characters such as CR and/or LF but this is possible. In such an event, the *lrecl* option must be specified accordingly.

Note: Unlike for the DOS and FIX types, the width of the fields is the length of their internal representation in the file. For instance for a column declared as:

```
number int(5) not null,
```

The field width in the file is 4 characters, the size of a binary integer. This is the value used to calculate the offset of the next field if it is not specified. Therefore, if the next field is placed 5 characters after this one, this declaration is not enough, and the flag option will have to be used on the next field.

Type Conversion in BIN Tables

Here are the correspondences between the column type and field format provided by default:

Column type	File default format
Char(n)	Text of n characters.
Date	Integer (4 bytes)
Int(n)	Integer (4 bytes)
Smallint(n)	Short integer (2 bytes)
TinyInt(n)	Char (1 Byte)
Bigint(n)	Large integer (8 bytes)
Double(n,d)	Double floating point (8 bytes)

However, the column type need not necessarily match the field format within the table file. In particular, this occurs for field formats that correspond to numeric types that are not handled by CONNECT[2]. Indeed, BIN table files may internally contain float numbers or binary numbers of any byte length in big-endian or little-endian representation[3]. Also, as in DOS or FIX types tables, you may want to handle some character fields as numeric or vice versa.

This is why it is possible to specify the field format when it does not correspond to the column type default using the *field_format* column option in the CREATE TABLE statement. Here are the available field formats for BIN tables:

Field_format	Internal representation
[n]{L or B or H}[n]	n bytes binary number in little endian, big endian or host endian representation.

Field_format	Internal representation
C	Characters string (n bytes)
I	integer (4 bytes)
D	Double float (8 bytes)
S	Short integer (2 bytes)
T	Tiny integer (1 byte)
G	Big integer (8 bytes)
F or R	Real or float (Floating point number on 4 bytes)
X	Use the default format field for the column type

All field formats (except the first one) are a one-character specification[4].
'X' is equivalent to not specifying the field format. For the 'C' character specification, *n* is the column width as specified with the column type. For one-column formats, the number of bytes of the numeric fields corresponds to what it is on most platforms. However, it could vary for some. The G, I, S and T formats are deprecated because they correspond to supported data types and may not be supported in future versions.

Example

Here is an example of a BIN table. The file record layout is supposed to be:

```
NNNNCCCCCCCCCCIIIISSFFFFSS
```

Here N represents numeric characters, C any characters, I integer bytes,
S short integer bytes, and F float number bytes. The `IIII` field contains a date in numeric format.

The table could be created by:

```
CREATE TABLE testbal (
fig INT(4) NOT NULL field_format='C',
name CHAR(10) NOT NULL,
birth DATE NOT NULL field_format='L',
id CHAR(5) NOT NULL field_format='L2',
salary DOUBLE(9,2) NOT NULL DEFAULT 0.00 field_format='F',
dept INT(4) NOT NULL field_format='L2')
ENGINE=CONNECT table_type=BIN block_size=5 file_name='Testbal.dat';
```

Specifying the little-endian representation for binary values is not useful on most machines, but makes the create table statement portable on a machine using big endian, as well as the table file.

The field offsets and the file record length are calculated according the column internal format and eventually modified by the field format. It is not necessary to specify them for a packed binary file without line endings. If a line ending is desired, specify the ending option or specify the `lrecl` option adding the ending width. The table can be filled by:

```
INSERT INTO testbal VALUES
  (5500,'ARCHIBALD','1980-01-25','3789',4380.50,318),
  (123,'OLIVER','1953-08-10','23456',3400.68,2158),
  (3123,'FOO','2002-07-23','888',default,318);
```

Note that the types of the inserted values must match the column type, not the field format type.

The query:

```
SELECT * FROM testbal;
```

returns:

fig	name	birth	id	salary	dept
5500	ARCHIBALD	1980-01-25	3789	4380.50	318
123	OLIVER	1953-08-10	23456	3400.68	2158
3123	FOO	2002-07-23	888	0.00	318

Numeric fields alignment

In binary files, numeric fields and record length can be aligned on 4-or-8-byte boundaries to optimize performance on certain processors. This can be modified in the OPTION_LIST with an “align” option (“packed” meaning `align=1` is the default).

1. ↑ Sometimes it can be a physical record if LF or CRLF have been written in the file.
2. ↑ Most of these are obsolete because CONNECT supports all column types except float
3. ↑ The default endian representation used in the table file can be specified by setting the ENDIAN option as ‘L’ or ‘B’ in the option list.
4. ↑ It can be specified with more than one character, but only the first one is significant.

CONNECT CSV and FMT Table Types

CSV Type

Many source data files are formatted with variable length fields and records.
The simplest format, known as `CSV` (Comma Separated Variables), has column fields separated by a separator character. By default, the separator is a comma but can be specified by the `SEP_CHAR` option as any character, for instance a semi-colon.

If the CSV file first record is the list of column names, specifying the `HEADER=1` option will skip the first record on reading. On writing, if the file is empty, the column names record is automatically written.

For instance, given the following *people.csv* file:

```
Name;birth;children
"Archibald";17/05/01;3
"Nabucho";12/08/03;2
```

You can create the corresponding table by:

```
CREATE TABLE people (
  name CHAR(12) NOT NULL,
  birth DATE NOT NULL date_format='DD/MM/YY',
  children SMALLINT(2) NOT NULL)
ENGINE=CONNECT table_type=CSV file_name='people.csv'
header=1 sep_char=';' quoted=1;
```

Alternatively the engine can attempt to automatically detect the column names, data types and widths using:

```
CREATE TABLE people
ENGINE=CONNECT table_type=CSV file_name='people.csv'
header=1 sep_char=';' quoted=1;
```

For CSV tables, the *flag* column option is the rank of the column into the file starting from 1 for the leftmost column. This is to enable having column displayed in a different order than in the file and/or to define the table specifying

only some columns of the CSV file. For instance:

```
CREATE TABLE people (
  name CHAR(12) NOT NULL,
  children SMALLINT(2) NOT NULL flag=3,
  birth DATE NOT NULL flag=2 date_format='DD/MM/YY')
ENGINE=CONNECT table_type=CSV file_name='people.csv'
header=1 sep_char=';' quoted=1;
```

In this case the command:

```
SELECT * FROM people;
```

will display the table as:

name	children	birth
Archibald	3	2001-05-17
Nabucho	2	2003-08-12

Many applications produce CSV files having some fields quoted, in particular because the field text contains the separator character. For such files, specify the 'QUOTED=*n*' option to indicate the level of quoting and/or the '`QCHAR=c`' to specify what is this eventual quoting character, which is `"` by default. Quoting with single quotes must be specified as `QCHAR=''''`. On writing, fields are quoted depending on the value of the quoting level, which is `-1` by default meaning no quoting:

0	The fields between quotes are read and the quotes discarded. On writing, fields are quoted only if they contain the separator character or begin with the quoting character. If they contain the quoting character, it are doubled.
1	Only text fields are written between quotes, except null fields. This includes also the column names of an eventual header.
2	All fields are written between quotes, except null fields.
3	All fields are written between quotes, including null fields.

Files written this way are successfully read by most applications including spreadsheets.

Note 1: If only the QCHAR option is specified, the QUOTED option will default to 1.

Note 2: For CSV tables whose separator is the tab character, specify `sep_char='\t'`.

Note 3: When creating a table on an existing CSV file, you can let CONNECT analyze the file and make the column description. However, this is a not an elaborate analysis of the file and, for instance, `DATE` fields will not be recognized as such but are regarded as string fields.

Note 4: The CSV parser only reads and buffers up to 4KB per row by default, rows longer than this is truncated when read from the file. If the rows are expected to be longer than this use `lrecl` to increase this. For example to set an 8KB maximum row read you would use `lrecl=8192`

Restrictions on CSV Tables

- If secure_file_priv is set to the path of some directory, then CSV tables can only be created with files in that directory.

FMT Type

FMT tables handle files of various formats that are an extension of the concept of CSV files. CONNECT supports these files providing all lines have the same format and that all fields present in all records are recognizable (optional fields must have recognizable delimiters). These files are made by specific application and CONNECT handles them in read only mode.

FMT tables must be created as CSV tables, specifying their type as FMT. In addition, each column description must be added to its format specification.

Column Format Specification of FMT tables

The input format for each column is specified as a FIELD_FORMAT option. A simple example is:

```
IP Char(15) not null field_format=' %n%s%n',
```

In the above example, the format for this (1st) field is `' %n%s%n'`. Note that the blank character at the beginning of this format **is** significant. No trailing blank should be specified in the column formats.

The syntax and meaning of the column input format is the one of the C **scanf** function.

However, CONNECT uses the input format in a specific way. Instead of using it to directly store the input value in the column buffer; it uses it to delimit the sub string of the input record that contains the corresponding column value. Retrieving this value is done later by the column functions as for standard CSV files.

This is why all column formats are made of five components:

1. An eventual description of what is met and ignored before the column value.
2. A marker of the beginning of the column value written as `%n`.
3. The format specification of the column value itself.
4. A marker of the end of the column value written as `%n` (or `%m` for optional fields).
5. An eventual description of what is met after the column value (not valid is `%m` was used).

For example, taking the file *funny.txt*:

```
12345,'BERTRAND',#200;5009.13
 56, 'POIROT-DELMOTTE' ,#4256 ;18009
345 ,'TRUCMUCHE' , #67; 19000.25
```

You can make a table *fmtsample* with 4 columns ID, NAME, DEPNO and SALARY, using the Create Table statement and column formats:

```
CREATE TABLE FMTSAMPLE (
  ID INTEGER(5) NOT NULL field_format=' %n%d%n',
  NAME CHAR(16) NOT NULL field_format=' , ''%n%[^'']%n''',
  DEPNO INTEGER(4) NOT NULL field_format=' , #%n%d%n',
  SALARY DOUBLE(12,2) NOT NULL field_format=' ; %n%f%n')
ENGINE=CONNECT table_type=FMT file_name='funny.txt';
```

Field 1 is an integer (`%d`) with eventual leading blanks.

Field 2 is separated from field 1 by optional blanks, a comma, and other optional blanks and is between single quotes. The leading quote is included in component 1 of the column format, followed by the `%n` marker. The column value is specified as `%[^pg-connect-connect-table-types-connect-csv-and-fmt-table-types-7399dbd1-']` meaning to keep any characters read until a quote is met. The ending marker (`%n`) is followed by the 5th component of the column format, the single quote that follows the column value.

Field 3, also separated by a comma, is a number preceded by a pound sign.

Field 4, separated by a semicolon eventually surrounded by blanks, is a number with an optional decimal point (`%f`).

This table are displayed as:

ID	NAME	DEPNO	SALARY
12345	BERTRAND	200	5009.13

ID	NAME	DEPNO	SALARY
56	POIROT-DELMOTTE	4256	18009.00
345	TRUCMUCHE	67	19000.25

Optional Fields

To be recognized, a field normally must be at least one character long. For instance, a numeric field must have at least one digit, or a character field cannot be void. However many existing files do not follow this format.

Let us suppose for instance that the preceding example file could be:

```
12345,'BERTRAND',#200;5009.13
 56, 'POIROT-DELMOTTE' ,# ;18009
345 ,'' , #67; 19000.25
```

This will display an error message such as *"Bad format line x field y of FMTSAMPLE".* To avoid this and accept these records, the corresponding fields must be specified as "optional". In the above example, fields 2 and 3 can have null values (in lines 3 and 2 respectively). To specify them as optional, their format must be terminated by `%m` (instead of the second `%n`). A statement such as this can do the table creation:

```
CREATE TABLE FMTAMPLE (
  ID INTEGER(5) NOT NULL field_format=' %n%d%n',
  NAME CHAR(16) NOT NULL field_format=' , ''%n%[^''']%m',
  DEPNO INTEGER(4) field_format=''' , #%n%d%m',
  SALARY DOUBLE(12,2) field_format=' ; %n%f%n')
ENGINE=CONNECT table_type=FMT file_name='funny.txt';
```

Note that, because the statement must be terminated by `%m` with no additional characters, skipping the ending quote of field 2 was moved from the end of the second column format to the beginning of the third column format.

The table result is:

ID	NAME	DEPNO	SALARY
12345	BERTRAND	200	5,009.13
56	POIROT-DELMOTTE	NULL	18,009.00
345	NULL	67	19,000.25

Missing fields are replaced by null values if the column is nullable, blanks for character strings and 0 for numeric fields if it is not.

Note 1: Because the formats are specified between quotes, quotes belonging to the formats must be doubled or escaped to avoid a `CREATE TABLE` statement syntax error.

Note 2: Characters separating columns can be included as well in component
5 of the preceding column format or in component 1 of the succeeding column format but for blanks, which should be always included in component 1 of the succeeding column format because line trailing blanks can be sometimes lost.
This is also mandatory for optional fields.

Note 3: Because the format is mainly used to find the sub-string corresponding to a column value, the field specification does not necessarily match the column type. For instance supposing a table contains two integer columns, NBONE and NBTWO, the two lines describing these columns could be:

```
NBONE integer(5) not null field_format=' %n%d%n',
NBTWO integer(5) field_format=' %n%s%n',
```

The first one specifies a required integer field (`%d`), the second line describes a field that can be an integer, but can be replaced by a “-” (or any other) character. Specifying the format specification for this column as a character field (`%s`) enables to recognize it with no error in all cases. Later on, this field are converted to integer by the column read function, and a null 0 value are generated for field specified in their format as non-numeric.

Bad Record Error Processing

When no match if found for a column field the process aborts with a message such as:

```
Bad format line 3 field 4 of funny.txt
```

This can mean as well that one line of the input line is ill formed or that the column format for this field has been wrongly specified. When you know that your file contains records that are ill formatted and should be eliminated from normal processing, set the “maxerr” option of the CREATE TABLE statement, for instance:

```
Option_list='maxerr=100'
```

This will indicate that no error message be raised for the 100 first wrong lines. You can set Maxerr to a number greater than the number of wrong lines in your files to ignore them and get no errors.

Additionally, the “accept” option permit to keep those ill formatted lines with the bad field, and all succeeding fields of the record, nullified. If “accept” is specified without “maxerr”, all ill formatted lines are accepted.

Note: This error processing also applies to CSV tables.

Fields Containing a Formatted Date

A special case is one of columns containing a formatted date. In this case, two formats must be specified:

1. The field recognition format used to delimit the date in the input record.
2. The date format used to interpret the date.
3. The field length option if the date representation is different than the standard type size.

For example, let us suppose we have a web log source file containing records such as:

```
165.91.215.31 - - [17/Jul/2001:00:01:13 -0400] - "GET /usnews/home.htm HTTP/1.1" 302
```

The create table statement shall be like this:

```
CREATE TABLE WEBSAMP (
  IP CHAR(15) NOT NULL field_format='%n%s%n',
  DATE DATETIME NOT NULL field_format=' - - [%n%s%n -0400]'
  date_format='DD/MMM/YYYY:hh:mm:ss' field_length=20,
  FILE CHAR(128) NOT NULL field_format=' - "GET %n%s%n',
  HTTP DOUBLE(4,2) NOT NULL field_format=' HTTP/%n%f%n"',
  NBONE INT(5) NOT NULL field_format=' %n%d%n')
ENGINE=CONNECT table_type=FMT lrecl=400
file_name='e:\\data\\token\\Websamp.dat';
```

Note 1: Here, `field_length=20` was necessary because the default size for datetime columns is only 19. The `lrecl=400` was also specified because the actual file contains more information in each records making the record size calculated by default too small.

Note 2: The file name could have been specified as `'e:/data/token/Websamp.dat'` .

Note 3: FMT tables are currently read only.

CONNECT DBF Table Type

Overview

A table of type `DBF` is physically a dBASE III or IV formatted file (used by many products like dBASE, Xbase, FoxPro etc.). This format is similar to the FIX type format with in addition a prefix giving the characteristics of the file, describing in particular all the fields (columns) of the table.

Because `DBF` files have a header that contains Meta data about the file, in particular the column description, it is possible to create a table based on an existing `DBF` file without giving the column description, for instance:

```
CREATE TABLE cust ENGINE=CONNECT table_type=DBF file_name='cust.dbf';
```

To see what CONNECT has done, you can use the `DESCRIBE` or `SHOW CREATE TABLE` statements, and eventually modify some options with the `ALTER TABLE` statement.

The case of deleted lines is handled in a specific way for DBF tables. Deleted lines are not removed from the file but are “soft deleted” meaning they are marked as deleted. In particular, the number of lines contained in the file header does not take care of soft deleted lines. This is why if you execute these two commands applied to a DBF table named *tabdbf*:

```
SELECT COUNT(*) FROM tabdbf;
SELECT COUNT(*) FROM tabdbf WHERE 1;
```

They can give a different result, the (fast) first one giving the number of physical lines in the file and the second one giving the number of line that are not (soft) deleted.

The commands `UPDATE`, `INSERT`, and `DELETE` can be used with DBF tables. The `DELETE` statement marks the deleted lines as suppressed but keeps them in the file. The `INSERT` statement, if it is used to populate a newly created table, constructs the file header before inserting new lines.

Note: For DBF tables, column name length is limited to 11 characters and field length to 256 bytes.

Conversion of dBASE Data Types

CONNECT handles only types that are stored as characters.

Symbol	DBF Type	CONNECT Type	Description
B	Binary (string)	TYPE_STRING	10 digits representing a .DBT block number.
C	Character	TYPE_STRING	All OEM code page characters - padded with blanks to the width of the field.
D	Date	TYPE_DATE	8 bytes - date stored as a string in the format YYYYMMDD.
N	Numeric	TYPE_INT TYPE_BIGINT TYPE_DOUBLE	Number stored as a string, right justified, and padded with blanks to the width of the field.
L	Logical	TYPE_STRING	1 byte - initialized to 0x20 otherwise T or F.
M	Memo (string)	TYPE_STRING	10 digits representing a .DBT block number.
@	Timestamp	Not supported	8 bytes - two longs, first for date, second for time. It is the number of days since 01/01/4713 BC.
I	Long	Not supported	4 bytes. Leftmost bit used to indicate sign, 0 negative.
+	Autoincrement	Not supported	Same as a Long

Symbol	DBF Type	CONNECT Type	Description
F	Float	TYPE_DOUBLE	Number stored as a string, right justified, and padded with blanks to the width of the field.
O	Double	Not supported	8 bytes - no conversions, stored as a double.
G	OLE	TYPE_STRING	10 digits representing a .DBT block number.

For the N numeric type, CONNECT converts it to `TYPE_DOUBLE` if the decimals value is not 0, to `TYPE_BIGINT` if the length value is greater than 10, else to TYPE_INT.

For M, B, and G types, CONNECT just returns the DBT number.

Reading soft deleted lines of a DBF table

It is possible to read these lines by changing the read mode of the table. This is specified by an option `READMODE` that can take the values:

0	Standard mode. This is the default option.
1	Read all lines including soft deleted ones.
2	Read only the soft deleted lines.

For example, to read all lines of the tabdbf table, you can do:

```
ALTER TABLE tabdbf option_list='Readmode=1';
```

To come back to normal mode, specify `READMODE=0`.

CONNECT DOS and FIX Table Types

Overview

Tables of type DOS and FIX are based on text files (see CONNECT Table Types - Data Files). Within a record, column fields are positioned at a fixed offset from the beginning of the record. Except sometimes for the last field, column fields are also of fixed length. If the last field has varying length, the type of the table is DOS. For instance, having the file *dept.dat* formatted like:

```
0318 KINGSTON       70012 SALES       Bank/Insurance
0021 ARMONK         87777 CHQ         Corporate headquarter
0319 HARRISON       40567 SALES       Federal Administration
2452 POUGHKEEPSIE   31416 DEVELOPMENT Research & development
```

You can define a table based on it with:

```
CREATE TABLE department (
  NUMBER CHAR(4) NOT NULL,
  LOCATION CHAR(15) NOT NULL flag=5,
  director CHAR(5) NOT NULL flag=20,
  FUNCTION CHAR(12) NOT NULL flag=26,
  name CHAR(22) NOT NULL flag=38)
ENGINE=CONNECT table_type=DOS file_name='dept.dat';
```

Here the flag column option represents the offset of this column inside the records. If the offset of a column is not specified, it defaults to the end of the previous column and defaults to 0 for the first one. The *`lrecl`* parameter that represents the maximum size of a record is calculated by default as the end of the rightmost column and can be unspecified except when some trailing information exists after the rightmost column.

Note: A special case is files having an encoding such as UTF-8 (for instance specifying `charset=UTF8`) in which some characters may be represented with several bytes. Unlike the type size that MariaDB interprets as a number of characters, the `lrecl` value is the record size in bytes and the flag value represents the offset of the field in the record in bytes. If the flag and/or the `lrecl` value are not specified, they are calculated by the number of characters in the fields multiplied by a value that is the maximum size in bytes of a character for the corresponding charset. For UTF-8 this value is 3 which is often far too much as there are very few characters requiring 3 bytes to be represented. When creating a new file, you are on the safe side by only doubling the maximum number of characters of a field to calculate the offset of the next field. Of course, for already existing files, the offset must be specified according to what it is in it.

Although the field representation is always text in the table file, you can freely choose the corresponding column type, characters, date, integer or floating point according to its contents.

Sometimes, as in the *number* column of the above *department* table, you have the choice of the type, numeric or characters. This will modify how the column is internally handled — in characters `0021` is different from `21` but not in numeric — as well as how it is displayed.

If the last field has fixed length, the table should be referred as having the type `FIX`. For instance, to create a table on the file *boys.txt*:

```
John      Boston      25/01/1986  02/06/2010
Henry     Boston      07/06/1987  01/04/2008
George    San Jose    10/08/1981  02/06/2010
Sam       Chicago     22/11/1979  10/10/2007
James     Dallas      13/05/1992  14/12/2009
Bill      Boston      11/09/1986  10/02/2008
```

You can for instance use the command:

```
CREATE TABLE boys (
  name CHAR(12) NOT NULL,
  city CHAR(12) NOT NULL,
  birth DATE NOT NULL date_format='DD/MM/YYYY',
  hired DATE NOT NULL date_format='DD/MM/YYYY' flag=36)
ENGINE=CONNECT table_type=FIX file_name='boys.txt' lrecl=48;
```

Here some *flag* options were not specified because the fields have no intermediate space between them except for the last column. The offsets are calculated by default adding the field length to the *offset* of the preceding field. However, for formatted date columns, the offset in the file depends on the format and cannot be calculated by default. For fixed files, the *lrecl* option is the physical length of the record including the line ending character(s). It is calculated by adding to the end of the last field 2 bytes under Windows (CRLF) or 1 byte under UNIX. If the file is imported from another operating system, the `ENDING` option will have to be specified with the proper value.

For this table, the last offset and the record length must be specified anyway because the date columns have field length coming from their format that is not known by CONNECT. Do not forget to add the line ending length to the total length of the fields.

This table is displayed as:

name	city	birth	hired
John	Boston	1986-01-25	2010-06-02
Henry	Boston	1987-06-07	2008-04-01
George	San Jose	1981-08-10	2010-06-02
Sam	Chicago	1979-11-22	2007-10-10
James	Dallas	1992-05-13	2009-12-14

name	city	birth	hired
Bill	Boston	1986-09-11	2008-02-10

Whenever possible, the fixed format should be preferred to the varying one because it is much faster to deal with fixed tables than with variable tables.
Sure enough, instead of being read or written record by record, FIX tables are processed by blocks of `BLOCK_SIZE` records, resulting in far less input/output operations to execute. The block size defaults to 100 if not specified in the Create Table statement.

Note 1: It is not mandatory to declare in the table all the fields existing in the source file. However, if some fields are ignored, the *flag* option of the following field and/or the *lrecl* option will have to be specified.

Note 2: Some files have an EOF marker (CTRL+Z 1A) that can prevent the table to be recognized as fixed because the file length is not a multiple of the fixed record size. To indicate this, use in the option list the create option EOF. For instance, if after creating the FIX table *xtab* on the file *foo.dat* that you know have fixed record size, you get, when you try to use it, a message such as:

```
File foo.dat is not fixed length, len=302587 lrecl=141
```

After checking that the LRECL default or specified specification is correct, you can indicate to ignore that extra EOF character by:

```
ALTER TABLE xtab option_list='eof=1';
```

Of course, you can specify this option directly in the Create statement. All this applies to some other table types, in particular to BIN tables.

Note 3: The width of the fields is the length specified in the column declaration. For instance for a column declared as:

```
number int(3) not null,
```

The field width in the file is 3 characters. This is the value used to calculate the offset of the next field if it is not specified. If this length is not specified, it defaults to the MySQL default type length.

Specifying the Field Format

Some files have specific format for their numeric fields. For instance, the decimal point is absent and/or the field should be filled with leading zeros.
To deal with such files, as well in reading as in writing, the format can be specified in the `CREATE TABLE` column definition. The syntax of the field format specification is:

```
Field_format='[Z][N][d]'
```

The optional parts of the format are:

Z	The field has leading zeros
N	No decimal point exist in the file
d	The number of decimals, defaults to the column precision

Example

Let us see how it works in the following example. We define a table based on the file xfmt.txt having eight fields of 12 characters:

```
CREATE TABLE xfmt (
  col1 DOUBLE(12,3) NOT NULL,
  col2 DOUBLE(12,3) NOT NULL field_format='4',
  col3 DOUBLE(12,2) NOT NULL field_format='N3',
  col4 DOUBLE(12,3) NOT NULL field_format='Z',
  col5 DOUBLE(12,3) NOT NULL field_format='Z3',
  col6 DOUBLE(12,5) NOT NULL field_format='ZN5',
  col7 INT(12) NOT NULL field_format='N3',
  col8 SMALLINT(12) NOT NULL field_format='N3')
ENGINE=CONNECT table_type=FIX file_name='xfmt.txt';

INSERT INTO xfmt VALUES(4567.056,4567.056,4567.056,4567.056,-23456.8,
    3.14159,4567,4567);
SELECT * FROM xfmt;
```

The first row is displayed as:

COL1	COL2	COL3	COL4	COL5	COL6	COL7	COL8
4567.056	4567.056	4567.06	4567.056	-23456.800	3.14159	4567	4567

The number of decimals displayed for all float columns is the column precision, the second argument of the column type option. Of course, integer columns have no decimals, although their formats specify some.

More interesting is the file layout. To see it let us define another table based on the same file but whose columns are all characters:

```
CREATE TABLE cfmt (
  col1 CHAR(12) NOT NULL,
  col2 CHAR(12) NOT NULL,
  col3 CHAR(12) NOT NULL,
  col4 CHAR(12) NOT NULL,
  col5 CHAR(12) NOT NULL,
  col6 CHAR(12) NOT NULL,
  col7 CHAR(12) NOT NULL,
  col8 CHAR(12) NOT NULL)
ENGINE=CONNECT table_type=FIX file_name='xfmt.txt';
SELECT * FROM cfmt;
```

The (transposed) display of the select command shows the file text layout for each field. Below a third column was added in this document to comment this result.

Column	Row 1	Comment (all numeric fields are written right justified)
COL1	4567.056	No format, the value was entered as is.
COL2	4567.0560	The format '4' forces to write 4 decimals.
COL3	4567060	N3 → No decimal point. The last 3 digits are decimals. However, the second decimal was rounded because of the column precision.
COL4	00004567.056	Z → Leading zeros, 3 decimals (the column precision)
COL5	-0023456.800	Z3 → (Minus sign) leading zeros, 3 decimals.
COL6	000000314159	ZN5 → Leading zeros, no decimal point, 5 decimals.
COL7	4567000	N3 → No decimal point. The last 3 digits are decimals.
COL8	4567000	Same. Any decimals would be ignored.

Note: For columns internally using double precision floating-point numbers,
MariaDB limits the decimal precision of any calculation to the column precision. The declared column precision

should be at least the number of decimals of the format to avoid a loss of decimals as it happened for `col3` of the above example.

CONNECT - External Table Types

Because so many ODBC and JDBC drivers exist and only the main ones have been heavily tested, these table types cannot be ranked as stable. Use them with care in production applications.

These types can be used to access tables belonging to the current or another database server. Six types are currently provided:

ODBC: To be used to access tables from a database management system providing an ODBC connector. ODBC is a standard of Microsoft and is currently available on Windows. On Linux, it can also be used provided a specific application emulating ODBC is installed. Currently only unixODBC is supported.

JDBC: To be used to access tables from a database management system providing a JDBC connector. JDBC is an Oracle standard implemented in Java and principally meant to be used by Java applications. Using it directly from C or C++ application seems to be almost impossible due to an Oracle bug still not fixed. However, this can be achieved using a Java wrapper class used as an interface between C++ and JDBC. On another hand, JDBC is available on all platforms and operating systems.

Mongo: To access MongoDB collections as tables via their MongoDB C Driver. Because this requires both MongoDB and the C Driver to be installed and operational, this table type is not currently available in binary distributions but only when compiling MariaDB from source.

MySQL: This type is the preferred way to access tables belonging to another MySQL or MariaDB server. It uses the MySQL API to access the external table. Even though this can be obtained using the FEDERATED(X) plugin, this specific type is used internally by CONNECT because it also makes it possible to access tables belonging to the current server.

PROXY: Internally used by some table types to access other tables from one table.

External Table Specification

The four main external table types – odbc, jdbc, mongo and mysql – are specified giving the following information:

1. The data source. This is specified in the connection option.
2. The remote table or view to access. This can be specified within the connection string or using specific CONNECT options.
3. The column definitions. This can be also left to CONNECT to find them using the discovery MariaDB feature.
4. The optional Quoted option. Can be set to 1 to quote the identifiers in the query sent to the remote server. This is required if columns or table names can contain blanks.

The way this works is by establishing a connection to the external data source and by sending it an SQL statement (or its equivalent using API functions for MONGO) enabling it to execute the original query. To enhance performance, it is necessary to have the remote data source do the maximum processing. This is needed in particular to reduce the amount of data returned by the data source.

This is why, for SELECT queries, CONNECT uses the cond_push MariaDB feature to retrieve the maximum of the where clause of the original query that can be added to the query sent to the data source. This is automatic and does not require anything to be done by the user.

However, more can be done. In addition to accessing a remote table, CONNECT offers the possibility to specify what the remote server must do. This is done by specifying it as a view in the srcdef option:

```
CREATE TABLE custnum ENGINE=CONNECT TABLE_TYPE=XXX
CONNECTION='connecton string'
SRCDEF='select pays as country, count(*) as customers from custnum group by pays';
```

Doing so, the group by clause are done by the remote server considerably reducing the amount of data sent back on the connection.

This may even be increased by adding to the srcdef part of the “compatible” part of the query where clauses like this are done for table-based tables. Note that for MariaDB, this table has two columns, country and customers. Supposing the original query is:

```
SELECT * FROM custnum WHERE (country = 'UK' OR country = 'USA') AND customers > 5;
```

How can we make the where clause be added to the sent srcdef? There are many problems:

1. Where to include the additional information.
2. What about the use of alias.
3. How to know what are a where clause or a having clause.

The first problem is solved by preparing the srcdef view to receive clauses. The above example srcdef becomes:

```
SRCDEF='select pays as country, count(*) as customers from custnum where %s group by pays having %s';
```

The *%s* in the srcdef are place holders for eventual compatible parts of the original query where clause. If the select query does not specify a where clause, or a gives an unacceptable where clause, place holders are filled by dummy clauses (1=1).

The other problems must be solved by adding to the create table a list of columns that must be translated because they are aliases or/and aliases on aggregate functions that must become a having clause. For example, in this case:

```
CREATE TABLE custnum ENGINE=CONNECT TABLE_TYPE=XXX
CONNECTION='connecton string'
SRCDEF='select pays as country, count(*) as customers from custnum where %s group by pays having %s'
OPTION_LIST='Alias=customers=*count(*);country=pays';
```

This is specified by the alias option, to be used in the option list. It is made of a semi-colon separated list of items containing:

1. The local column name (alias in the remote server)
2. An equal sign.
3. An eventual ‘*’ indicating this is column correspond to an aggregate function.
4. The remote column name.

With this information, CONNECT are able to make the query sent to the remote data source:

```
SELECT pays AS country, COUNT(*) AS customers FROM custnum WHERE (pays = 'UK' OR pays = 'USA') GROUP BY
country HAVING COUNT(*) > 5
```

Note: Some data sources, including MySQL and MariaDB, accept aliases in the having clause. In that case, the alias option could have been specified as:

```
OPTION_LIST='Alias=customers=*;country=pays';
```

Another option exists, phpos, enabling to specify what place holders are present and in what order. To be specified as “W”, “WH”, “H”, or “HW”. It is rarely used because by default CONNECT can set it from the srcdef content. The only cases it is needed is when the srcdef contains only a having place holder or when the having place holder

occurs before the where place holder, which can occur on queries containing joins. CONNECT cannot handle more than one place holder of each type.

SRCDEF is not available for MONGO tables, but other ways of achieving this exist and are described in the MONGO table type chapter.

CONNECT - Files Retrieved Using Rest Queries

> **Warning:**
>
> This storage engine has been deprecated.

Starting with CONNECT version 1.07.0001, JSON, XML and possibly CSV data files can be retrieved as results from REST queries when creating or querying such tables. This is done internally by CONNECT using the CURL program generally available on all systems (if not just install it).

This can also be done using the Microsoft Casablanca (cpprestsdk) package. To enable it, first, install the package as explained in cpprestsdk. Then make the GetRest library (dll or so) as explained in Making the GetRest Library.

Note: If both are available, cpprestsdk is used preferably because it is faster. This can be changed by specifying 'curl=1' in the option list.

Note: If you want to use this feature with an older distributed version of MariaDB not featuring REST, it is possible to add it as an OEM module as explained in Adding the REST Feature as a Library Called by an OEM Table.

Creating Tables using REST

To do so, specify the HTTP of the web client and eventually the URI of the request in the CREATE TABLE statement. For example, for a query returning JSON data:

```
CREATE TABLE webusers (
  id BIGINT(2) NOT NULL,
  name CHAR(24) NOT NULL,
  username CHAR(16) NOT NULL,
  email CHAR(25) NOT NULL,
  address VARCHAR(256) DEFAULT NULL,
  phone CHAR(21) NOT NULL,
  website CHAR(13) NOT NULL,
  company VARCHAR(256) DEFAULT NULL
) ENGINE=CONNECT DEFAULT CHARSET=utf8
TABLE_TYPE=JSON FILE_NAME='users.json' HTTP='http://jsonplaceholder.typicode.com' URI='/users';
```

As with standard JSON tables, discovery is possible, meaning that you can leave CONNECT to define the columns by analyzing the JSON file. Here you could just do:

```
CREATE TABLE webusers
ENGINE=CONNECT DEFAULT CHARSET=utf8
TABLE_TYPE=JSON FILE_NAME='users.json'
HTTP='http://jsonplaceholder.typicode.com' URI='/users';
```

For example, executing:

```
SELECT name, address FROM webusers2 LIMIT 1;
```

returns:

name	address
Leanne Graham	Kulas Light Apt. 556 Gwenborough 92998-3874 -37.3159 81.1496

Here we see that for some complex elements such as *address*, which is a Json object containing values and objects, CONNECT by default has just listed their texts separated by blanks. But it is possible to ask it to analyze in more depth the json result by adding the DEPTH option. For instance:

```
CREATE OR REPLACE TABLE webusers
ENGINE=CONNECT DEFAULT CHARSET=utf8
TABLE_TYPE=JSON FILE_NAME='users.json'
HTTP='http://jsonplaceholder.typicode.com' URI='/users'
OPTION_LIST='Depth=2';
```

Then the table are created as:

```
CREATE TABLE `webusers3` (
  `id` BIGINT(2) NOT NULL,
  `name` CHAR(24) NOT NULL,
  `username` CHAR(16) NOT NULL,
  `email` CHAR(25) NOT NULL,
  `address_street` CHAR(17) NOT NULL `JPATH`='$.address.street',
  `address_suite` CHAR(9) NOT NULL `JPATH`='$.address.suite',
  `address_city` CHAR(14) NOT NULL `JPATH`='$.address.city',
  `address_zipcode` CHAR(10) NOT NULL `JPATH`='$.address.zipcode',
  `address_geo_lat` CHAR(8) NOT NULL `JPATH`='$.address.geo.lat',
  `address_geo_lng` CHAR(9) NOT NULL `JPATH`='$.address.geo.lng',
  `phone` CHAR(21) NOT NULL,
  `website` CHAR(13) NOT NULL,
  `company_name` CHAR(18) NOT NULL `JPATH`='$.company.name',
  `company_catchPhrase` CHAR(40) NOT NULL `JPATH`='$.company.catchPhrase',
  `company_bs` VARCHAR(36) NOT NULL `JPATH`='$.company.bs'
) ENGINE=CONNECT DEFAULT CHARSET=utf8 `TABLE_TYPE`='JSON' `FILE_NAME`='users.json'
`OPTION_LIST`='Depth=2' `HTTP`='http://jsonplaceholder.typicode.com' `URI`='/users';
```

Allowing one to get all the values of the Json result, for example:

```
SELECT name, address_city city, company_name company FROM webusers3;
```

That results in:

name	city	company
Leanne Graham	Gwenborough	Romaguera-Crona
Ervin Howell	Wisokyburgh	Deckow-Crist
Clementine Bauch McKenziehaven	Romaguera-Jacobson	
Patricia Lebsack	South Elvis	Robel-Corkery
Chelsey Dietrich	Roscoeview	Keebler LLC
Mrs. Dennis Schulist	South Christy	Considine-Lockman
Kurtis Weissnat	Howemouth	Johns Group
Nicholas Runolfsdottir V	Aliyaview	Abernathy Group
Glenna Reichert	Bartholomebury	Yost and Sons
Clementina DuBuque	Lebsackbury	Hoeger LLC

Of course, the complete create table (obtained by SHOW CREATE TABLE) can later be edited to make your table return exactly what you want to get. See the JSON table type for details about what and how to specify these.

Note that such tables are read only. In addition, the data are retrieved from the web each time you query the table with a SELECT statement. This is fine if the result varies each time, such as when you query a weather forecasting site. But if you want to use the retrieved file many times without reloading it, just create another table on the same file without specifying the HTTP option.

Note: For JSON tables, specifying the file name is optional and defaults to tabname.type. However, you should specify it if you want to use the file later for other tables.

See the JSON table type for changes that will occur in the new CONNECT versions (distributed in early 2021).

CONNECT INI Table Type

Overview

The INI type is one of the configuration or initialization files often found on
Windows machines. For instance, let us suppose you have the following contact file *contact.ini*:

```
[BER]
name=Bertrand
forename=Olivier
address=21 rue Ferdinand Buisson
city=Issy-les-Mlx
zipcode=92130
tel=09.54.36.29.60
cell=06.70.06.04.16

[WEL]
name=Schmitt
forename=Bernard
hired=19/02/1985
address=64 tiergarten strasse
city=Berlin
zipcode=95013
tel=03.43.377.360

[UK1]
name=Smith
forename=Henry
hired=08/11/2003
address=143 Blum Rd.
city=London
zipcode=NW1 2BP
```

CONNECT lets you view it as a table in two different ways.

Column Layout

The first way is to regard it as a table having one line per section, the columns being the keys you want to display. In this case, the `CREATE` statement could be:

```
CREATE TABLE contact (
  contact CHAR(16) flag=1,
  name CHAR(20),
  forename CHAR(32),
  hired DATE date_format='DD/MM/YYYY',
  address CHAR(64),
  city CHAR(20),
  zipcode CHAR(8),
  tel CHAR(16))
ENGINE=CONNECT table_type=INI file_name='contact.ini';
```

The column that will contain the section name can have any name but must specify `flag=1`. All other columns must have the names of the keys we want to display (case insensitive). The type can be character or numeric depending on the key value type, and the length is the maximum expected length for the key value. Once done, the statement:

```
SELECT contact, name, hired, city, tel FROM contact;
```

This statement will display the file in tabular format.

contact	name	hired	city	tel
BER	Bertrand	1970-01-01	Issy-les-Mlx	09.54.36.29.60
WEL	Schmitt	1985-02-19	Berlin	03.43.377.360
UK1	Smith	2003-11-08	London	NULL

Only the keys defined in the create statements are visible; keys that do not exist in a section are displayed as null or pseudo null (blank for character, 1/1/70 for dates, and 0 for numeric) for columns declared `NOT NULL`.

All relational operations can be applied to this table. The table (and the file) can be updated, inserted and conditionally deleted. The only constraint is that when inserting values, the section name must be the first in the list of values.

Note 1: When inserting, if a section already exists, no new section are created but the new values are added or replace those of the existing section. Thus, the following two commands are equivalent:

```
UPDATE contact SET forename = 'Harry' WHERE contact = 'UK1';
INSERT INTO contact (contact,forename) VALUES('UK1','Harry');
```

Note 2: Because sections represent one line, a DELETE statement on a section key will delete the whole section.

Row Layout

To be a good candidate for tabular representation, an INI file should have often the same keys in all sections. In practice, many files commonly found on computers, such as the *win.ini* file of the Windows directory or the_my.ini_ file cannot be viewed that way because each section has different keys. In this case, a second way is to regard the file as a table having one row per section key and whose columns can be the section name, the key name, and the key value.

For instance, let us define the table:

```
create table xcont (
  section char(16) flag=1,
  keyname char(16) flag=2,
  value char(32))
engine=CONNECT table_type=INI file_name='contact.ini'
option_list='Layout=Row';
```

In this statement, the “Layout” option sets the display format, Column by default or anything else not beginning by ‘C’ for row layout display. The names of the three columns can be freely chosen. The Flag option gives the meaning of the column. Specify `flag=1` for the section name and `flag=2` for the key name. Otherwise, the column will contain the key value.

Once done, the command:

```
SELECT * FROM xcont;
```

This displays the following result:

section	keyname	value
BER	name	Bertrand
BER	forename	Olivier
BER	address	21 rue Ferdinand Buisson
BER	city	Issy-les-Mlx

section	keyname	value
BER	zipcode	92130
BER	tel	09.54.36.29.60
BER	cell	06.70.06.04.16
WEL	name	Schmitt
WEL	forename	Bernard
WEL	hired	19/02/1985
WEL	address	64 tiergarten strasse
WEL	city	Berlin
WEL	zipcode	95013
WEL	tel	03.43.377.360
UK1	name	Smith
UK1	forename	Henry
UK1	hired	08/11/2003
UK1	address	143 Blum Rd.
UK1	city	London
UK1	zipcode	NW1 2BP

Note: When processing an INI table, all section names are retrieved in a buffer of 8K bytes (2048 bytes before 10.0.17). For a big file having many sections, this size can be increased using for example:

```
option_list='seclen=16K';
```

This page is licensed: CC BY-SA / Gnu FDL

CONNECT JDBC Table Type: Accessing Tables from Another DBMS

The JDBC table type should be distributed with all recent versions of MariaDB. However, if the automatic compilation of it is possible after the java JDK was installed, the complete distribution of it is not fully implemented in older versions. The distributed JdbcInterface.jar file contains the JdbcInterface wrapper only. New versions distribute a JavaWrappers.jar that contains all currently existing wrappers.

This will require that:

1. The Java SDK is installed on your system.
2. The java wrapper class files are available on your system.
3. And of course, some JDBC drivers exist to be used with the matching DBMS.

Point 2 was made automatic in the newest versions of MariaDB.

Compiling From Source Distribution

Even when the Java JDK has been installed, CMake sometimes cannot find the location where it stands. For instance on Linux the Oracle Java JDK package might be installed in a path not known by the CMake lookup functions causing error message such as:

```
CMake Error at /usr/share/cmake/Modules/FindPackageHandleStandardArgs.cmake:148 (message):
  Could NOT find Java (missing: Java_JAR_EXECUTABLE Java_JAVAC_EXECUTABLE
  Java_JAVAH_EXECUTABLE Java_JAVADOC_EXECUTABLE)
```

When this happen, provide a Java prefix as a hint on where the package was loaded. For instance on Ubuntu I was obliged to enter:

```
export JAVA_HOME=/usr/lib/jvm/java-8-oracle
```

After that, the compilation of the CONNECT JDBC type was completed successfully.

Compiling the Java source files

They are the source of the java wrapper classes used to access JDBC drivers. In the source distribution, they are located in the CONNECT source directory.

The default wrapper, JdbcInterface, is the only one distributed with binary distribution. It uses the standard way to get a connection to the drivers via the DriverManager.getConnection method. Other wrappers, only available with source distribution, enable connection to a Data Source, eventually implementing pooling. However, they must be compiled and installed manually.

The available wrappers are:

Wrapper	Description
JdbcInterface	Used to make the connection with available drivers the standard way.
ApacheInterface	Based on the Apache common-dbcp2 package this interface enables making connections to DBCP data sources with any JDBC drivers.
MariadbInterface	Makes connection to a MariaDB data source.
MysqlInterface	Makes connection to a Mysql data source. Must be used with a MySQL driver that implements data sources.
OracleInterface	Makes connection to an Oracle data source.
PostgresqlInterface	Makes connection to a Postgresql data source.

The wrapper used by default is specified by the connect_java_wrapper session variable and is initially set to `wrappers/JdbcInterface`. The wrapper to use for a table can also be specified in the option list as a wrapper option of the “create table” statements.

Note: Conforming java naming usage, class names are preceded by the java package name with a slash separator. However, this is not mandatory for CONNECT which adds the package name if it is missing.

The JdbcInterface wrapper is always usable when Java is present on your machine. Binary distributions have this wrapper already compiled as a JdbcInterface.jar file installed in the plugin directory whose path is automatically included in the class path of the JVM. Recent versions also add a JavaWrappers.jar that contains all these wrappers. Therefore there is no need to worry about its path.

Compiling the ApacheInterface wrapper requires that the Apache common-DBCP2 package be installed. Other wrappers are to be used only with the matching JDBC drivers that must be available when compiling them.

Installing the jar file in the plugin directory is the best place because it is part of the class path. Depending on what is installed on your system, the source files can be reduced accordingly. To compile only the JdbcInterface.java file the CMAKE_JAVA_INCLUDE_PATH is not required. Here the paths are the ones existing on my Windows 7 machine and should be localized.

Setting the Required Information

Before any operation with a JDBC driver can be made, CONNECT must initialize the environment that will make working with Java possible. This will consist of:

1. Loading dynamically the JVM library module.
2. Creating the Java Virtual Machine.

3. Establishing contact with the java wrapper class.
4. Connecting to the used JDBC driver.

Indeed, the JVM library module is not statically linked to the CONNECT plugin. This is to make it possible to use a CONNECT plugin that has been compiled with the JDBC table type on a machine where the Java SDK is not installed. Otherwise, users not interested in the JDBC table type would be obliged to install the Java SDK on their machine to be able to load the CONNECT storage engine.

JVM Library Location

If the JVM library (jvm.dll on Windows, libjvm.so on Linux) was not placed in the standard library load path, CONNECT cannot find it and must be told where to search for it. This happens in particular on Linux when the Oracle Javapackage was installed in a private location.

If the JAVA_HOME variable was exported as explained above, CONNECT can sometimes find it using this information. Otherwise, its search path can be added to the LD_LIBRARY_PATH environment variable. But all this is complicated because making environment variables permanent on Linux is painful (many different methods must be used depending on the Linux version and the used shell).

This is why CONNECT introduced a new global variable connect_jvm_path to store this information. It can be set when starting the server as a command line option or even afterwards before the first use of the JDBC table type:

```
set global connect_jvm_path="/usr/lib/jvm/java-8-oracle/jre/lib/i386/client"
```

or

```
set global connect_jvm_path="/usr/lib/jvm/java-8-oracle/jre/lib/i386/server"
```

The client library is smaller and faster for connection. The server library is more optimized and can be used in case of heavy load usage.

Note that this may not be required on Windows because the path to the JVM library can sometimes be found in the registry.

Once this library is loaded, CONNECT can create the required Java Virtual Machine.

Java Class Path

This is the list of paths Java searches when loading classes. With CONNECT, the classes to load are the java wrapper classes used to communicate with the drivers, and the used JDBC driver classes that are grouped inside jar files. If the ApacheInterface wrapper must be used, the class path must also include all three jars used by the Apache package.

Caution: This class path is passed as a parameter to the Java Virtual Machine (JVM) when creating it and cannot be modified as it is a read only property. In addition, because MariaDB is a multi-threading application, this JVM cannot be destroyed and are used throughout the entire life of the MariaDB server. Therefore, be sure it is correctly set before you use the JDBC table type for the first time. Otherwise, there are practically no alternative than to shut down the server and restart it.

The path to the wrapper classes must point to the directory containing the wrappers sub-directory. If a JdbcInterface.jar file was made, its path is the directory where it is located followed by the jar file name. It is unclear where because this will depend on the installation process. If you start from a source distribution, it can be in the storage/connect directory where the CONNECT source files are or where you moved them or compiled the JdbcInterface.jar file.

For binary distributions, there is nothing to do because the jar file has been installed in the mysql share directory whose path is always automatically included in the class path available to the JVM.

Remaining are the paths of all the installed JDBC drivers that you intend to use. Remember that their path must include the jar file itself. Some applications use an environment variable CLASSPATH to contain them. Paths are separated by ':' on Linux and by ';' on Windows.

If the CLASSPATH variable actually exists and if it is available inside MariaDB, so far so good. You can check this using an UDF function provided by CONNECT that returns environment variable values:

```
CREATE FUNCTION envar RETURNS STRING soname 'ha_connect.so';
SELECT envar('CLASSPATH');
```

Most of the time, this will return null or some required files are missing. This is why CONNECT introduced a global variable to store this information. The paths specified in this variable are added and have precedence to the ones, if any, of the CLASSPATH environment variable. As for the jvm path, this variable connect_class_path should be specified when starting the server but can also be set before using the JDBC table type for the first time.

The current directory (sql/data) is also placed by CONNECT at the beginning of the class path.

As an example, here is how I start MariaDB when doing tests on Linux:

```
olivier@olivier-Aspire-8920:~$ sudo /usr/local/mysql/bin/mysqld -u root --console --default-storage-
engine=myisam --skip-innodb --connect_jvm_path="/usr/lib/jvm/java-8-oracle/jre/lib/i386/server" --
connect_class_path="/home/olivier/mariadb/10.1/storage/connect:/media/olivier/SOURCE/mysql-connector-
java-6.0.2/mysql-connector-java-6.0.2-bin.jar"
```

CONNECT JDBC Tables

These tables are given the type JDBC. For instance, supposing you want to access the boys table located on and external local or remote database management system providing a JDBC connector:

```
CREATE TABLE boys (
name CHAR(12),
city CHAR(12),
birth DATE,
hired DATE);
```

To access this table via JDBC you can create a table such as:

```
CREATE TABLE jboys ENGINE=CONNECT table_type=JDBC tabname=boys
CONNECTION='jdbc:mysql://localhost/dbname?user=root';
```

The CONNECTION option is the URL used to establish the connection with the remote server. Its syntax depends on the external DBMS and in this example is the one used to connect as root to a MySQL or MariaDB local database using the MySQL JDBC connector.

As for ODBC, the columns definition can be omitted and are retrieved by the discovery process. The restrictions concerning column definitions are the same as for ODBC.

Note: The dbname indicated in the URL corresponds for many DBMS to the catalog information. For MySQL and MariaDB it is the schema (often called database) of the connection.

Using a Federated Server

Alternatively, a JDBC table can specify its connection options via a Federated server. For instance, supposing you have a table accessing an external Postgresql table defined as:

```
CREATE TABLE juuid ENGINE=CONNECT table_type=JDBC tabname=testuuid
CONNECTION='jdbc:postgresql:test?user=postgres&password=pwd';
```

You can create a Federated server:

```
CREATE server 'post1' FOREIGN DATA wrapper 'postgresql' OPTIONS (
HOST 'localhost',
DATABASE 'test',
USER 'postgres',
PASSWORD 'pwd',
PORT 0,
SOCKET '',
OWNER 'postgres');
```

Now the JDBC table can be created by:

```
CREATE TABLE juuid ENGINE=CONNECT table_type=JDBC CONNECTION='post1' tabname=testuuid;
```

or by:

```
CREATE TABLE juuid ENGINE=CONNECT table_type=JDBC CONNECTION='post1/testuuid';
```

In any case, the location of the remote table can be changed in the Federated server without having to alter all the tables using this server.

JDBC needs a URL to establish a connection. CONNECT was able to construct that URL from the information contained in such Federated server definition when the URL syntax is similar to the one of MySQL, MariaDB or Postgresql. However, other DBMSs such as Oracle use a different URL syntax. In this case, simply replace the HOST information by the required URL in the Federated server definition. For instance:

```
CREATE server 'oracle' FOREIGN DATA wrapper 'oracle' OPTIONS (
HOST 'jdbc:oracle:thin:@localhost:1521:xe',
DATABASE 'SYSTEM',
USER 'system',
PASSWORD 'manager',
PORT 0,
SOCKET '',
OWNER 'SYSTEM');
```

Now you can create an Oracle table with something like this:

```
CREATE TABLE empor ENGINE=CONNECT table_type=JDBC CONNECTION='oracle/HR.EMPLOYEES';
```

Note: Oracle, as Postgresql, does not seem to understand the DATABASE setting as the table schema that must be specified in the Create Table statement.

Connecting to a JDBC driver

When the connection to the driver is established by the JdbcInterface wrapper class, it uses the options that are provided when creating the CONNECT JDBC tables. Inside the default Java wrapper, the driver's main class is loaded by the DriverManager.getConnection function that takes three arguments:

URL	User	Password
URL	That is the URL that you specified in the CONNECTION option.	
User	As specified in the OPTION_LIST or NULL if not specified.	
Password	As specified in the OPTION_LIST or NULL if not specified.	

The URL varies depending on the connected DBMS. Refer to the documentation of the specific JDBC driver for a description of the syntax to use. User and password can also be specified in the option list.

Beware that the database name in the URL can be interpreted differently depending on the DBMS. For MySQL this is the schema in which the tables are found. However, for Postgresql, this is the catalog and the schema must be specified using the CONNECT dbname option.

For instance a table accessing a Postgresql table via JDBC can be created with a create statement such as:

```
CREATE TABLE jt1 ENGINE=CONNECT table_type=JDBC
CONNECTION='jdbc:postgresql://localhost/mtr' dbname=PUBLIC tabname=t1
option_list='User=mtr,Password=mtr';
```

Note: In previous versions of JDBC, to obtain a connection, java first had to initialize the JDBC driver by calling the method Class.forName. In this case, see the documentation of your DBMS driver to obtain the name of the class that implements the interface java.sql.Driver. This name can be specified as an option DRIVER to be put in the option list. However, most modern JDBC drivers since version 4 are self-loading and do not require this option to be specified.

The wrapper class also creates some required items and, in particular, a statement class. Some characteristics of this statement will depend on the options specified when creating the table:

Scrollable	Block_size
Scrollable	To be specified in the option list. Determines the cursor type: no= forward_only or yes=scroll_insensitive.
Block_size	Will be used to set the statement fetch size.

Fetch Size

The fetch size determines the number of rows that are internally retrieved by the driver on each interaction with the DBMS. Its default value depends on the JDBC driver. It is equal to 10 for some drivers but not for the MySQL or MariaDB connectors.

The MySQL/MariaDB connectors retrieve all the rows returned by one query and keep them in a memory cache. This is generally fine in most cases, but not when retrieving a large result set that can make the query fail with a memory exhausted exception.

To avoid this, when accessing a big table and expecting large result sets, you should specify the BLOCK_SIZE option to 1 (the only acceptable value). However a problem remains:

Suppose you execute a query such as:

```
SELECT id, name, phone FROM jbig LIMIT 10;
```

Not knowing the limit clause, CONNECT sends to the remote DBMS the query:

```
SELECT id, name, phone FROM big;
```

In this query big can be a huge table having million rows. Having correctly specified the block size as 1 when creating the table, the wrapper just reads the 10 first rows and stops. However, when closing the statement, these MySQL/MariaDB drivers must still retrieve all the rows returned by the query. This is why, the wrapper class when closing the statement also cancels the query to stop that extra reading.

The bad news is that if it works all right for some previous versions of the MySQL driver, it does not work for new versions as well as for the MariaDB driver that apparently ignores the cancel command. The good news is that you can use an old MySQL driver to access MariaDB databases. It is also possible that this bug are fixed in future versions of the drivers.

Connection to a Data Source

This is the java preferred way to establish a connection because a data source can keep a pool of connections that can be reused when necessary. This makes establishing connections much faster once it was done for the first time.

CONNECT provide additional wrappers whose files are located in the CONNECT source directory. The wrapper to use can be specified in the global variable connect_java_wrapper, which defaults to “JdbcInterface”.

It can also be specified for a table in the option list by setting the option wrapper to its name. For instance:

```
CREATE TABLE jboys
ENGINE=CONNECT table_type=JDBC tabname='boys'
CONNECTION='jdbc:mariadb://localhost/connect?user=root&useSSL=false'
option_list='Wrapper=MariadbInterface,Scrollable=1';
```

They can be used instead of the standard JdbcInterface and are using created data sources.

The Apache one uses data sources implemented by the Apache-commons-dbcp2 package and can be used with all drivers including those not implementing data sources. However, the Apache package must be installed and its three required jar files accessible via the class path.

1. commons-dbcp2-2.1.1.jar
2. commons-pool2-2.4.2.jar
3. commons-logging-1.2.jar

Note: the versions numbers can be different on your installation.

The other ones use data sources provided by the matching JDBC driver. There are currently four wrappers to be used with mysql-6.0.2, mariadb, oracle and postgresql.

Unlike the class path, the used wrapper can be changed even after the JVM machine was created.

Random Access to JDBC Tables

The same methods described for ODBC tables can be used with JDBC tables.

Note that in the case of the MySQL or MariaDB connectors, because they internally read the whole result set in memory, using the MEMORY option would be a waste of memory. It is much better to specify the use of a scrollable cursor when needed.

Other Operations with JDBC Tables

Except for the way the connection string is specified and the table type set to JDBC, all operations with ODBC tables are done for JDBC tables the same way. Refer to the ODBC chapter to know about:

- Accessing specified views (SRCDEF)
- Data modifying operations.
- Sending commands to a data source.
- JDBC catalog information.

Note: Some JDBC drivers fail when the global time_zone variable is ambiguous, which sometimes happens when it is set to SYSTEM. If so, reset it to a not ambiguous value, for instance:

```
set global time_zone = '+2:00';
```

JDBC Specific Restrictions

Connecting via data sources created externally (for instance using Tomcat) is not supported yet.

Other restrictions are the same as for the ODBC table type.

Handling the UUID Data Type

PostgreSQL has a native UUID data type, internally stored as BIN(16). This is neither an SQL nor a MariaDB data type. The best we can do is to handle it by its character representation.

UUID are translated to CHAR(36) when column definitions are set using discovery. Locally a PostgreSQL UUID column are handled like a CHAR or VARCHAR column. Example:

Using the PostgreSQL table testuuid in the text database:

```
Table « public.testuuid »
 Column | Type | Default
--------+------+--------------------
 id     | uuid | uuid_generate_v4()
 msg    | text |
```

Its column definitions can be queried by:

```
CREATE OR REPLACE TABLE juuidcol ENGINE=CONNECT table_type=JDBC tabname=testuuid catfunc=columns
CONNECTION='jdbc:postgresql:test?user=postgres&password=pwd';
```

```
SELECT TABLE_NAME "Table", COLUMN_NAME "Column", data_type "Type",
  type_name "Name", column_size "Size"
 FROM juuidcol;
```

This query returns:

Table	Column	Type	Name	Size
testuuid	id	1111	uuid	2147483647
testuuid	msg	12	text	2147483647

Note: PostgreSQL, when a column size is undefined, returns 2147483647, which is not acceptable for MariaDB. CONNECT change it to the value of the connect_conv_size session variable. Also, for TEXT columns the data type returned is 12 (SQL_VARCHAR) instead of -1 the SQL_TEXT value.

Accessing this table via JDBC by:

```
CREATE TABLE juuid ENGINE=CONNECT TABLE_TYPE=JDBC TABNAME=testuuid
CONNECTION='jdbc:postgresql:test?user=postgres&password=pwd';
```

it are created by discovery as:

```
CREATE TABLE `juuid` (
  `id` CHAR(36) DEFAULT NULL,
  `msg` VARCHAR(8192) DEFAULT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 CONNECTION='jdbc:postgresql:test?user=postgres&password=pwd'
`TABLE_TYPE`='JDBC' `TABNAME`='testuuid';
```

Note: 8192 being here the *connect_conv_size* value.

Let's populate it:

```
INSERT INTO juuid(msg) VALUES('First');
INSERT INTO juuid(msg) VALUES('Second');
SELECT * FROM juuid;
```

Result:

id	msg
4b173ee1-1488-4355-a7ed-62ba59c2b3e7	First
6859f850-94a7-4903-8d3c-fc3c874fc274	Second

Here the id column values come from the DEFAULT of the PostgreSQL column that was specified as uuid_generate_v4().

It can be set from MariaDB. For instance:

```
INSERT INTO juuid
  VALUES('2f835fb8-73b0-42f3-a1d3-8a532b38feca','inserted');
INSERT INTO juuid VALUES(NULL,'null');
INSERT INTO juuid VALUES('','random');
SELECT * FROM juuid;
```

Result:

id	msg
4b173ee1-1488-4355-a7ed-62ba59c2b3e7	First
6859f850-94a7-4903-8d3c-fc3c874fc274	Second
2f835fb8-73b0-42f3-a1d3-8a532b38feca	inserted
	null
8fc0a30e-dc66-4b95-ba57-497a161f4180	random

The first insert specifies a valid UUID character representation. The second one set it to NULL. The third one (a void string) generates a Java random UUID. UPDATE commands obey the same specification.

These commands both work:

```
SELECT * FROM juuid WHERE id = '2f835fb8-73b0-42f3-a1d3-8a532b38feca';
DELETE FROM juuid WHERE id = '2f835fb8-73b0-42f3-a1d3-8a532b38feca';
```

However, this one fails:

```
SELECT * FROM juuid WHERE id like '%42f3%';
```

Returning:

1296: Got error 174 ’ExecuteQuery: org.postgresql.util.PSQLException:
ERROR: operator does not exist: uuid ~ unknown hint: no operator corresponds to the data name and to the argument types.

because CONNECT cond_push feature added the WHERE clause to the query sent to PostgreSQL:

```
SELECT id, msg FROM testuuid WHERE id LIKE '%42f3%'
```

and the LIKE operator does not apply to UUID in PostgreSQL.

To handle this, a new session variable was added to CONNECT: connect_cond_push. It permits to specify if cond_push is enabled or not for CONNECT and defaults to 1 (enabled). In this case, you can execute:

```
set connect_cond_push=0;
```

Doing so, the where clause are executed by MariaDB only and the query will not fail anymore.

Executing the JDBC tests

Four tests exist but they are disabled because requiring some work to localized them according to the operating system and available java package and JDBC drivers and DBMS.

Two of them, jdbc.test and jdbc_new.test, are accessing MariaDB via JDBC drivers that are contained in a fat jar file that is part of the test. They should be executable without anything to do on Windows; simply adding the option –enable-disabled when running the tests.

However, on Linux these tests can fail to locate the JVM library. Before executing them, you should export the JAVA_HOME environment variable set to the prefix of the java installation or export the LD_LIBRARY_PATH containing the path to the JVM lib.

Fixing Problem With mariadb-dump

In some case or some platform, when CONNECT is set up for use with JDBC table types, this causes mariadb-dump with the option –all-databases to fail.

This was reported by Robert Dyas who found the cause - see the discussion at MDEV-11238.

CONNECT JSON Table Type

Overview

JSON (JavaScript Object Notation) is a lightweight data-interchange format widely used on the Internet. Many applications, generally written in JavaScript or PHP use and produce JSON data, which are exchanged as files of different physical formats. JSON data is often returned from REST queries.

It is also possible to query, create or update such information in a database-like manner. MongoDB does it using a JavaScript-like language. PostgreSQL includes these facilities by using a specific data type and related functions like dynamic columns.

The CONNECT engine adds this facility to MariaDB by supporting tables based on JSON data files. This is done like for XML tables by creating tables describing what should be retrieved from the file and how it should be processed.

Starting with 1.07.0002, the internal way JSON was parsed and handled was changed. The main advantage of the new way is to reduce the memory required to parse JSON. It was from 6 to 10 times the size of the JSON source and is now only 2 to 4 times. However, this is in Beta mode and JSON tables are still handled using the old mode. To use the new mode, tables should be created with TABLE_TYPE=BSON. Another way is the set the connect_force_bson session variable to 1 or ON. Then all JSON tables are handled as BSON. Of course, this is temporary and when successfully tested, the new way will replace the old way and all tables be created as JSON.

Let us start from the file “biblio3.json” that is the JSON equivalent of the XML Xsample file described in the XML table chapter:

```
[
  {
    "ISBN": "9782212090819",
    "LANG": "fr",
    "SUBJECT": "applications",
    "AUTHOR": [
      {
        "FIRSTNAME": "Jean-Christophe",
        "LASTNAME": "Bernadac"
      },
      {
        "FIRSTNAME": "François",
        "LASTNAME": "Knab"
      }
    ],
    "TITLE": "Construire une application XML",
    "PUBLISHER": {
      "NAME": "Eyrolles",
      "PLACE": "Paris"
    },
    "DATEPUB": 1999
  },
  {
    "ISBN": "9782840825685",
    "LANG": "fr",
    "SUBJECT": "applications",
    "AUTHOR": [
      {
        "FIRSTNAME": "William J.",
        "LASTNAME": "Pardi"
      }
    ],
    "TITLE": "XML en Action",
    "TRANSLATED": {
       "PREFIX": "adapté de l'anglais par",
       "TRANSLATOR": {
          "FIRSTNAME": "James",
        "LASTNAME": "Guerin"
        }
    },
    "PUBLISHER": {
      "NAME": "Microsoft Press",
      "PLACE": "Paris"
    },
    "DATEPUB": 1999
  }
]
```

This file contains the different items existing in JSON.

- `Arrays` : They are enclosed in square brackets and contain a list of comma separated values.
- `Objects` : They are enclosed in curly brackets. They contain a comma separated list of pairs, each pair composed of a key name between double quotes, followed by a ':' character and followed by a value.
- `Values` : Values can be an array or an object. They also can be a string between double quotes, an integer or float number, a Boolean value or a null value.
  The simplest way for CONNECT to locate a table in such a file is by an array containing a list of objects (this is what MongoDB calls a collection of documents). Each array value are a table row and each pair of the row objects will represent a column, the key being the column name and the value the column value.

A first try to create a table on this file are to take the outer array as the table:

```
CREATE TABLE jsample (
ISBN CHAR(15),
LANG CHAR(2),
SUBJECT CHAR(32),
AUTHOR CHAR(128),
TITLE CHAR(32),
TRANSLATED CHAR(80),
PUBLISHER CHAR(20),
DATEPUB INT(4))
ENGINE=CONNECT table_type=JSON
File_name='biblio3.json';
```

If we execute the query:

```
SELECT isbn, author, title, publisher FROM jsample;
```

We get the result:

isbn	author	title	publisher
9782212090819	Jean-Christophe Bernadac	Construire une application XML	Eyrolles Paris
9782840825685	William J. Pardi	XML en Action	Microsoft Press Pari

Note that by default, column values that are objects have been set to the concatenation of all the string values of the object separated by a blank. When a column value is an array, only the first item of the array is retrieved (This will change in later versions of Connect).

However, things are generally more complicated. If JSON files do not contain attributes (although object pairs are similar to attributes) they contain a new item, arrays. We have seen that they can be used like XML multiple nodes, here to specify several authors, but they are more general because they can contain objects of different types, even it may not be advisable to do so.

This is why CONNECT enables the specification of a column field_format option “JPATH” (FIELD_FORMAT until Connect 1.6) that is used to describe exactly where the items to display are and how to handles arrays.

Here is an example of a new table that can be created on the same file, allowing choosing the column names, to get some sub-objects and to specify how to handle the author array.

Until Connect 1.5:

```
CREATE TABLE jsampall (
ISBN CHAR(15),
LANGUAGE CHAR(2) field_format='LANG',
Subject CHAR(32) field_format='SUBJECT',
Author CHAR(128) field_format='AUTHOR:[" and "]',
Title CHAR(32) field_format='TITLE',
TRANSLATION CHAR(32) field_format='TRANSLATOR:PREFIX',
Translator CHAR(80) field_format='TRANSLATOR',
Publisher CHAR(20) field_format='PUBLISHER:NAME',
LOCATION CHAR(16) field_format='PUBLISHER:PLACE',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

From Connect 1.6:

```
CREATE TABLE jsampall (
ISBN CHAR(15),
LANGUAGE CHAR(2) field_format='LANG',
Subject CHAR(32) field_format='SUBJECT',
Author CHAR(128) field_format='AUTHOR.[" and "]',
Title CHAR(32) field_format='TITLE',
TRANSLATION CHAR(32) field_format='TRANSLATOR.PREFIX',
Translator CHAR(80) field_format='TRANSLATOR',
Publisher CHAR(20) field_format='PUBLISHER.NAME',
LOCATION CHAR(16) field_format='PUBLISHER.PLACE',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

From Connect 1.07.0002

```
CREATE TABLE jsampall (
ISBN CHAR(15),
LANGUAGE CHAR(2) jpath='$.LANG',
Subject CHAR(32) jpath='$.SUBJECT',
Author CHAR(128) jpath='$.AUTHOR[" and "]',
Title CHAR(32) jpath='$.TITLE',
TRANSLATION CHAR(32) jpath='$.TRANSLATOR.PREFIX',
Translator CHAR(80) jpath='$.TRANSLATOR',
Publisher CHAR(20) jpath='$.PUBLISHER.NAME',
LOCATION CHAR(16) jpath='$.PUBLISHER.PLACE',
YEAR INT(4) jpath='$.DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

Given the query:

```
SELECT title, author, publisher, LOCATION FROM jsampall;
```

The result is:

title	author	publisher	location
Construire une application XML	Jean-Christophe Bernadac and François Knab	Eyrolles	Paris
XML en Action	William J. Pardi	Microsoft Press	Paris

Note: The JPATH was not specified for column ISBN because it defaults to the column name.

Here is another example showing that one can choose what to extract from the file and how to “expand” an array, meaning to generate one row for each array value:

Until Connect 1.5:

```
CREATE TABLE jsampex (
ISBN CHAR(15),
Title CHAR(32) field_format='TITLE',
AuthorFN CHAR(128) field_format='AUTHOR:[X]:FIRSTNAME',
AuthorLN CHAR(128) field_format='AUTHOR:[X]:LASTNAME',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

From Connect 1.6:

```
CREATE TABLE jsampex (
ISBN CHAR(15),
Title CHAR(32) field_format='TITLE',
AuthorFN CHAR(128) field_format='AUTHOR.[X].FIRSTNAME',
AuthorLN CHAR(128) field_format='AUTHOR.[X].LASTNAME',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

From Connect 1.06.006:

```
CREATE TABLE jsampex (
ISBN CHAR(15),
Title CHAR(32) field_format='TITLE',
AuthorFN CHAR(128) field_format='AUTHOR[*].FIRSTNAME',
AuthorLN CHAR(128) field_format='AUTHOR[*].LASTNAME',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

From Connect 1.07.0002

```
CREATE TABLE jsampex (
ISBN CHAR(15),
Title CHAR(32) jpath='TITLE',
AuthorFN CHAR(128) jpath='AUTHOR[*].FIRSTNAME',
AuthorLN CHAR(128) jpath='AUTHOR[*].LASTNAME',
YEAR INT(4) jpath='DATEPUB')
ENGINE=CONNECT table_type=JSON File_name='biblio3.json';
```

It is displayed as:

ISBN	Title	AuthorFN	AuthorLN	Year
9782212090819	Construire une application XML	Jean-Christophe	Bernadac	1999
9782212090819	Construire une application XML	François	Knab	1999
9782840825685	XML en Action	William J.	Pardi	1999

Note: The example above shows that the '$.', that means the beginning of the path, can be omitted.

The Jpath Specification

From Connect 1.6, the Jpath specification has changed to be the one of the native JSON functions and more compatible with what is generally used. It is close to the standard definition and compatible to what MongoDB and other products do. The ':' separator is replaced by '.'. Position in array is accepted MongoDB style with no square brackets. Array specification specific to CONNECT are still accepted but [*] is used for expanding and [x] for multiply. However, tables created with the previous syntax can still be used by adding SEP_CHAR=':' (can be done with alter table). Also, it can be now specified as JPATH (was FIELD_FORMAT) but FIELD_FORMAT is still accepted.

Until Connect 1.5, it is the description of the path to follow to reach the required item. Each step is the key name (case sensitive) of the pair when crossing an object, and the number of the value between square brackets when crossing an array. Each specification is separated by a ':' character.

From Connect 1.6, It is the description of the path to follow to reach the required item. Each step is the key name (case sensitive) of the pair when crossing an object, and the position number of the value when crossing an array. Key specifications are separated by a '.' character.

For instance, in the above file, the last name of the second author of a book is reached by:

$.AUTHOR[1].LASTNAME *standard style$AUTHOR.1.LASTNAME* MongoDB style
AUTHOR:[1]:LASTNAME *old style when SEP_CHAR=':' or until Connect 1.5*

The '$' or "$." prefix specifies the root of the path and can be omitted with CONNECT.

The array specification can also indicate how it must be processed:

For instance, in the above file, the last name of the second author of a book is reached by:

```
AUTHOR:[1]:LASTNAME
```

The array specification can also indicate how it must be processed:

Specification	Array Type	Limit	Description
n (Connect >= 1.6) or [n][1]	All	N.A	Take the nth value of the array.
[*] (Connect >= 1.6), [X] or [x] (Connect <= 1.5)	All		Expand. Generate one row for each array value.
[“string”]	String		Concatenate all values separated by the specified string.
[+]	Numeric		Make the sum of all the non-null array values.
[x] (Connect >= 1.6), [*] (Connect <= 1.5)	Numeric		Make the product of all non-null array values.
[!]	Numeric		Make the average of all the non-null array values.
[>] or [<]	All		Return the greatest or least non-null value of the array.
[#]	All	N.A	Return the number of values in the array.
[]	All		Expand if under an expanded object. Otherwise sum if numeric, else concatenation separated by “, “.
	All		Between two separators, if an array, expand it if under an expanded object or take the first value of it.

Note 1: When the LIMIT restriction is applicable, only the first *m* array items are used, *m* being the value of the LIMIT option (to be specified in option_list). The LIMIT default value is 10.

Note 2: An alternative way to indicate what is to be expanded is to use the expand option in the option list, for instance:

```
OPTION_LIST='Expand=AUTHOR'
```

`AUTHOR` is here the key of the pair that has the array as a value (case sensitive). Expand is limited to only one branch (expanded arrays must be under the same object).

Let us take as an example the file `expense.json` (found here).
The table jexpall expands all under and including the week array:

From Connect 1.07.0002

```
CREATE TABLE jexpall (
WHO CHAR(12),
WEEK INT(2) jpath='$.WEEK[*].NUMBER',
WHAT CHAR(32) jpath='$.WEEK[*].EXPENSE[*].WHAT',
AMOUNT DOUBLE(8,2) jpath='$.WEEK[*].EXPENSE[*].AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

From Connect.1.6

```
CREATE TABLE jexpall (
WHO CHAR(12),
WEEK INT(2) field_format='$.WEEK[*].NUMBER',
WHAT CHAR(32) field_format='$.WEEK[*].EXPENSE[*].WHAT',
AMOUNT DOUBLE(8,2) field_format='$.WEEK[*].EXPENSE[*].AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

Until Connect 1.5:

```
CREATE TABLE jexpall (
WHO CHAR(12),
WEEK INT(2) field_format='WEEK:[x]:NUMBER',
WHAT CHAR(32) field_format='WEEK:[x]:EXPENSE:[x]:WHAT',
AMOUNT DOUBLE(8,2) field_format='WEEK:[x]:EXPENSE:[x]:AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

WHO	WEEK	WHAT	AMOUNT
Joe	3	Beer	18.00
Joe	3	Food	12.00
Joe	3	Food	19.00
Joe	3	Car	20.00
Joe	4	Beer	19.00
Joe	4	Beer	16.00
Joe	4	Food	17.00
Joe	4	Food	17.00
Joe	4	Beer	14.00
Joe	5	Beer	14.00
Joe	5	Food	12.00
Beth	3	Beer	16.00
Beth	4	Food	17.00
Beth	4	Beer	15.00
Beth	5	Food	12.00
Beth	5	Beer	20.00
Janet	3	Car	19.00
Janet	3	Food	18.00
Janet	3	Beer	18.00
Janet	4	Car	17.00
Janet	5	Beer	14.00
Janet	5	Car	12.00
Janet	5	Beer	19.00
Janet	5	Food	12.00

The table `jexpw` shows what was bought and the sum and average of amounts for each person and week:

From Connect 1.07.0002

```
CREATE TABLE jexpw (
WHO CHAR(12) NOT NULL,
WEEK INT(2) NOT NULL jpath='$.WEEK[*].NUMBER',
WHAT CHAR(32) NOT NULL jpath='$.WEEK[].EXPENSE[", "].WHAT',
SUM DOUBLE(8,2) NOT NULL jpath='$.WEEK[].EXPENSE[+].AMOUNT',
AVERAGE DOUBLE(8,2) NOT NULL jpath='$.WEEK[].EXPENSE[!].AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

From Connect 1.6:

```
CREATE TABLE jexpw (
WHO CHAR(12) NOT NULL,
WEEK INT(2) NOT NULL field_format='$.WEEK[*].NUMBER',
WHAT CHAR(32) NOT NULL field_format='$.WEEK[].EXPENSE[", "].WHAT',
SUM DOUBLE(8,2) NOT NULL field_format='$.WEEK[].EXPENSE[+].AMOUNT',
AVERAGE DOUBLE(8,2) NOT NULL field_format='$.WEEK[].EXPENSE[!].AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

Until Connect 1.5:

```
CREATE TABLE jexpw (
WHO CHAR(12) NOT NULL,
WEEK INT(2) NOT NULL field_format='WEEK:[x]:NUMBER',
WHAT CHAR(32) NOT NULL field_format='WEEK::EXPENSE:[", "]:WHAT',
SUM DOUBLE(8,2) NOT NULL field_format='WEEK::EXPENSE:[+]:AMOUNT',
AVERAGE DOUBLE(8,2) NOT NULL field_format='WEEK::EXPENSE:[!]:AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

WHO	WEEK	WHAT	SUM	AVERAGE
Joe	3	Beer, Food, Food, Car	69.00	17.25
Joe	4	Beer, Beer, Food, Food, Beer	83.00	16.60
Joe	5	Beer, Food	26.00	13.00
Beth	3	Beer	16.00	16.00
Beth	4	Food, Beer	32.00	16.00
Beth	5	Food, Beer	32.00	16.00
Janet	3	Car, Food, Beer	55.00	18.33
Janet	4	Car	17.00	17.00
Janet	5	Beer, Car, Beer, Food	57.00	14.25

Let us see what the table `jexpz` does:

From Connect 1.6:

```
CREATE TABLE jexpz (
WHO CHAR(12) NOT NULL,
WEEKS CHAR(12) NOT NULL field_format='WEEK[", "].NUMBER',
SUMS CHAR(64) NOT NULL field_format='WEEK["+"].EXPENSE[+].AMOUNT',
SUM DOUBLE(8,2) NOT NULL field_format='WEEK[+].EXPENSE[+].AMOUNT',
AVGS CHAR(64) NOT NULL field_format='WEEK["+"].EXPENSE[!].AMOUNT',
SUMAVG DOUBLE(8,2) NOT NULL field_format='WEEK[+].EXPENSE[!].AMOUNT',
AVGSUM DOUBLE(8,2) NOT NULL field_format='WEEK[!].EXPENSE[+].AMOUNT',
AVERAGE DOUBLE(8,2) NOT NULL field_format='WEEK[!].EXPENSE[*].AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

From Connect 1.07.0002

```
CREATE TABLE jexpz (
WHO CHAR(12) NOT NULL,
WEEKS CHAR(12) NOT NULL jpath='WEEK[", "].NUMBER',
SUMS CHAR(64) NOT NULL jpath='WEEK["+"].EXPENSE[+].AMOUNT',
SUM DOUBLE(8,2) NOT NULL jpath='WEEK[+].EXPENSE[+].AMOUNT',
AVGS CHAR(64) NOT NULL jpath='WEEK["+"].EXPENSE[!].AMOUNT',
SUMAVG DOUBLE(8,2) NOT NULL jpath='WEEK[+].EXPENSE[!].AMOUNT',
AVGSUM DOUBLE(8,2) NOT NULL jpath='WEEK[!].EXPENSE[+].AMOUNT',
AVERAGE DOUBLE(8,2) NOT NULL jpath='WEEK[!].EXPENSE[*].AMOUNT')
ENGINE=CONNECT table_type=JSON File_name='expense.json';
```

Until Connect 1.5:

```
CREATE TABLE jexpz (
WHO CHAR(12) NOT NULL,
WEEKS CHAR(12) NOT NULL field_format='WEEK:[", "]:NUMBER',
SUMS CHAR(64) NOT NULL field_format='WEEK:["+"]:EXPENSE:[+]:AMOUNT',
SUM DOUBLE(8,2) NOT NULL field_format='WEEK:[+]:EXPENSE:[+]:AMOUNT',
AVGS CHAR(64) NOT NULL field_format='WEEK:["+"]:EXPENSE:[!]:AMOUNT',
SUMAVG DOUBLE(8,2) NOT NULL field_format='WEEK:[+]:EXPENSE:[!]:AMOUNT',
AVGSUM DOUBLE(8,2) NOT NULL field_format='WEEK:[!]:EXPENSE:[+]:AMOUNT',
AVERAGE DOUBLE(8,2) NOT NULL field_format='WEEK:[!]:EXPENSE:[x]:AMOUNT')
ENGINE=CONNECT table_type=JSON
File_name='E:/Data/Json/expense2.json';
```

WHO	WEEKS	SUMS	SUM	AVGS	SUMAVG	AVGSUM	AVERAGE
Joe	3, 4, 5	69.00+83.00+26.00	178.00	17.25+16.60+13.00	46.85	59.33	16.18
Beth	3, 4, 5	16.00+32.00+32.00	80.00	16.00+16.00+16.00	48.00	26.67	16.00
Janet	3, 4, 5	55.00+17.00+57.00	129.00	18.33+17.00+14.25	49.58	43.00	16.12

For all persons:

- Column 1 show the person name.
- Column 2 shows the weeks for which values are calculated.
- Column 3 lists the sums of expenses for each week.
- Column 4 calculates the sum of all expenses by person.
- Column 5 shows the week's expense averages.
- Column 6 calculates the sum of these averages.
- Column 7 calculates the average of the week's sum of expenses.
- Column 8 calculates the average expense by person.

It would be very difficult, if even possible, to obtain this result from table `jexpall` using an SQL query.

Handling of NULL Values

Json has a null explicit value that can be met in arrays or object key values. When regarding json as a relational table, a column value can be null because the corresponding json item is explicitly null, or implicitly because the corresponding item is missing in an array or object. CONNECT does not make any distinction between explicit and implicit nulls.

However, it is possible to specify how nulls are handled and represented. This is done by setting the string session variable connect_json_null. The default value of connect_json_null is “”; it can be changed, for instance, by:

```
SET connect_json_null='NULL';
```

This changes its representation when a column displays the text of an object or the concatenation of the values of an array.

It is also possible to tell CONNECT to ignore nulls by:

```
SET connect_json_null=NULL;
```

When doing so, nulls do not appear in object text or array lists. However, this does not change the behavior of array calculation nor the result of array count.

Having Columns defined by Discovery

It is possible to let the MariaDB discovery process do the job of column specification. When columns are not defined in the create table statement, CONNECT endeavors to analyze the JSON file and to provide the column

specifications. This is possible only for tables represented by an array of objects because CONNECT retrieves the column names from the object pair keys and their definition from the object pair values. For instance, the jsample table could be created saying:

```
CREATE TABLE jsample ENGINE=CONNECT table_type=JSON file_name='biblio3.json';
```

Let's check how it was actually specified using the show create table statement:

```
CREATE TABLE `jsample` (
  `ISBN` CHAR(13) NOT NULL,
  `LANG` CHAR(2) NOT NULL,
  `SUBJECT` CHAR(12) NOT NULL,
  `AUTHOR` VARCHAR(256) DEFAULT NULL,
  `TITLE` CHAR(30) NOT NULL,
  `TRANSLATED` VARCHAR(256) DEFAULT NULL,
  `PUBLISHER` VARCHAR(256) DEFAULT NULL,
  `DATEPUB` INT(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='JSON' `FILE_NAME`='biblio3.json';
```

It is equivalent except for the column sizes that have been calculated from the file as the maximum length of the corresponding column when it was a normal value. For columns that are json arrays or objects, the column is specified as a varchar string of length 256, supposedly big enough to contain the sub-object's concatenated values. Nullable is set to true if the column is null or missing in some rows or if its JPATH contains arrays.

If a more complex definition is desired, you can ask CONNECT to analyse the JPATH up to a given depth using the DEPTH or LEVEL option in the option list. Its default value is 0 but can be changed setting the connect_default_depth session variable (in future versions the default are 5). The depth value is the number of sub-objects that are taken in the JPATH2 (this is different from what is defined and returned by the native Json_Depth function).

For instance:

```
CREATE TABLE jsampall2 ENGINE=CONNECT table_type=JSON
  file_name='biblio3.json' option_list='level=1';
```

This will define the table as:

From Connect 1.07.0002

```
CREATE TABLE `jsampall2` (
  `ISBN` CHAR(13) NOT NULL,
  `LANG` CHAR(2) NOT NULL,
  `SUBJECT` CHAR(12) NOT NULL,
  `AUTHOR_FIRSTNAME` CHAR(15) NOT NULL `JPATH`='$.AUTHOR.[0].FIRSTNAME',
  `AUTHOR_LASTNAME` CHAR(8) NOT NULL `JPATH`='$.AUTHOR.[0].LASTNAME',
  `TITLE` CHAR(30) NOT NULL,
  `TRANSLATED_PREFIX` CHAR(23) DEFAULT NULL `JPATH`='$.TRANSLATED.PREFIX',
  `TRANSLATED_TRANSLATOR` VARCHAR(256) DEFAULT NULL `JPATH`='$.TRANSLATED.TRANSLATOR',
  `PUBLISHER_NAME` CHAR(15) NOT NULL `JPATH`='$.PUBLISHER.NAME',
  `PUBLISHER_PLACE` CHAR(5) NOT NULL `JPATH`='$.PUBLISHER.PLACE',
  `DATEPUB` INT(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='JSON'
  `FILE_NAME`='biblio3.json' `OPTION_LIST`='depth=1';
```

From Connect 1.6:

```
CREATE TABLE `jsampall2` (
  `ISBN` CHAR(13) NOT NULL,
  `LANG` CHAR(2) NOT NULL,
  `SUBJECT` CHAR(12) NOT NULL,
  `AUTHOR_FIRSTNAME` CHAR(15) NOT NULL `FIELD_FORMAT`='AUTHOR..FIRSTNAME',
  `AUTHOR_LASTNAME` CHAR(8) NOT NULL `FIELD_FORMAT`='AUTHOR..LASTNAME',
  `TITLE` CHAR(30) NOT NULL,
  `TRANSLATED_PREFIX` CHAR(23) DEFAULT NULL `FIELD_FORMAT`='TRANSLATED.PREFIX',
  `TRANSLATED_TRANSLATOR` VARCHAR(256) DEFAULT NULL `FIELD_FORMAT`='TRANSLATED.TRANSLATOR',
  `PUBLISHER_NAME` CHAR(15) NOT NULL `FIELD_FORMAT`='PUBLISHER.NAME',
  `PUBLISHER_PLACE` CHAR(5) NOT NULL `FIELD_FORMAT`='PUBLISHER.PLACE',
  `DATEPUB` INT(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='JSON'
  `FILE_NAME`='biblio3.json' `OPTION_LIST`='level=1';
```

Until Connect 1.5:

```
CREATE TABLE `jsampall2` (
  `ISBN` CHAR(13) NOT NULL,
  `LANG` CHAR(2) NOT NULL,
  `SUBJECT` CHAR(12) NOT NULL,
  `AUTHOR_FIRSTNAME` CHAR(15) NOT NULL `FIELD_FORMAT`='AUTHOR::FIRSTNAME',
  `AUTHOR_LASTNAME` CHAR(8) NOT NULL `FIELD_FORMAT`='AUTHOR::LASTNAME',
  `TITLE` CHAR(30) NOT NULL,
  `TRANSLATED_PREFIX` CHAR(23) DEFAULT NULL `FIELD_FORMAT`='TRANSLATED:PREFIX',
  `TRANSLATED_TRANSLATOR` VARCHAR(256) DEFAULT NULL `FIELD_FORMAT`='TRANSLATED:TRANSLATOR',
  `PUBLISHER_NAME` CHAR(15) NOT NULL `FIELD_FORMAT`='PUBLISHER:NAME',
  `PUBLISHER_PLACE` CHAR(5) NOT NULL `FIELD_FORMAT`='PUBLISHER:PLACE',
  `DATEPUB` INT(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='JSON' `
  FILE_NAME`='biblio3.json' `OPTION_LIST`='level=1';
```

For columns that are a simple value, the Json path is the column name. This is the default when the Jpath option is not specified, so it was not specified for such columns. However, you can force discovery to specify it by setting the connect_all_path variable to 1 or ON. This can be useful if you plan to change the name of such columns and relieves you of manually specifying the path (otherwise it would default to the new name and cause the column to not or wrongly be found).

Another problem is that CONNECT cannot guess what you want to do with arrays. Here the AUTHOR array is set to 0, which means that only its first value are retrieved unless you also had specified “Expand=AUTHOR” in the option list. But of course, you can replace it with anything else.

This method can be used as a quick way to make a “template” table definition that can later be edited to make the desired definition. In particular, column names are constructed from all the object keys of their path in order to have distinct column names. This can be manually edited to have the desired names, provided their JPATH key names are not modified.

DEPTH can also be given the value -1 to create only columns that are simple values (no array or object). It normally defaults to 0 but this can be modified setting the connect_default_depth variable.

Note: Since version 1.6.4, CONNECT eliminates columns that are “void” or whose type cannot be determined. For instance given the file sresto.json:

```
{"_id":1,"name":"Corner Social","cuisine":"American","grades":[{"grade":"A","score":6}]}
{"_id":2,"name":"La Nueva Clasica Antillana","cuisine":"Spanish","grades":[]}
```

Previously, when using discovery, creating the table by:

```
CREATE TABLE sjr0
ENGINE=CONNECT table_type=JSON file_name='sresto.json'
option_list='Pretty=0,Depth=1' lrecl=128;
```

The table was previously created as:

```
CREATE TABLE `sjr0` (
  `_id` BIGINT(1) NOT NULL,
  `name` CHAR(26) NOT NULL,
  `cuisine` CHAR(8) NOT NULL,
  `grades` CHAR(1) DEFAULT NULL,
  `grades_grade` CHAR(1) DEFAULT NULL `JPATH`='$.grades[0].grade',
  `grades_score` BIGINT(1) DEFAULT NULL `JPATH`='$.grades[0].score'
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='JSON'
  `FILE_NAME`='sresto.json'
  `OPTION_LIST`='Pretty=0,Depth=1,Accept=1' `LRECL`=128;
```

The column “grades” was added because of the void array in line 2. Now this column is skipped and does not appear anymore (unless the option `Accept=1` is added in the option list).

JSON Catalogue Tables

Another way to see JSON table column specifications is to use a catalogue table. For instance:

```
CREATE TABLE bibcol ENGINE=CONNECT table_type=JSON file_name='biblio3.json'
  option_list='level=2' catfunc=columns;
SELECT COLUMN_NAME, type_name TYPE, column_size SIZE, jpath FROM bibcol;
```

which returns:

From Connect 1.07.0002:

column_name	type	size	jpath
ISBN	CHAR	13	$.ISBN
LANG	CHAR	2	$.LANG
SUBJECT	CHAR	12	$.SUBJECT
AUTHOR_FIRSTNAME	CHAR	15	$.AUTHOR[0].FIRSTNAME
AUTHOR_LASTNAME	CHAR	8	$.AUTHOR[0].LASTNAME
TITLE	CHAR	30	$.TITLE
TRANSLATED_PREFIX	CHAR	23	$.TRANSLATED.PREFIX
TRANSLATED_TRANSLATOR_FIRSTNAME	CHAR	5	$TRANSLATED.TRANSLATOR.FIRSTNAME
TRANSLATED_TRANSLATOR_LASTNAME	CHAR	6	$.TRANSLATED.TRANSLATOR.LASTNAME
PUBLISHER_NAME	CHAR	15	$.PUBLISHER.NAME
PUBLISHER_PLACE	CHAR	5	$.PUBLISHER.PLACE
DATEPUB	INTEGER	4	$.DATEPUB

From Connect 1.6:

column_name	type	size	jpath
ISBN	CHAR	13	
LANG	CHAR	2	
SUBJECT	CHAR	12	
AUTHOR_FIRSTNAME	CHAR	15	AUTHOR..FIRSTNAME
AUTHOR_LASTNAME	CHAR	8	AUTHOR..LASTNAME
TITLE	CHAR	30	
TRANSLATED_PREFIX	CHAR	23	TRANSLATED.PREFIX

column_name	type	size	jpath
TRANSLATED_TRANSLATOR_FIRSTNAME	CHAR	5	TRANSLATED.TRANSLATOR.FIRSTNAME
TRANSLATED_TRANSLATOR_LASTNAME	CHAR	6	TRANSLATED.TRANSLATOR.LASTNAME
PUBLISHER_NAME	CHAR	15	PUBLISHER.NAME
PUBLISHER_PLACE	CHAR	5	PUBLISHER.PLACE
DATEPUB	INTEGER	4	

Until Connect 1.5:

column_name	type	size	jpath
ISBN	CHAR	13	
LANG	CHAR	2	
SUBJECT	CHAR	12	
AUTHOR_FIRSTNAME	CHAR	15	AUTHOR::FIRSTNAME
AUTHOR_LASTNAME	CHAR	8	AUTHOR::LASTNAME
TITLE	CHAR	30	
TRANSLATED_PREFIX	CHAR	23	TRANSLATED:PREFIX
TRANSLATED_TRANSLATOR_FIRSTNAME	CHAR	5	TRANSLATED:TRANSLATOR:FIRSTNAME
TRANSLATED_TRANSLATOR_LASTNAME	CHAR	6	TRANSLATED:TRANSLATOR:LASTNAME
PUBLISHER_NAME	CHAR	15	PUBLISHER:NAME
PUBLISHER_PLACE	CHAR	5	PUBLISHER:PLACE
DATEPUB	INTEGER	4	

All this is mostly useful when creating a table on a remote file that you cannot easily see.

Finding the table within a JSON file

Given the file “facebook.json”:

```
{
   "data": [
      {
         "id": "X999_Y999",
         "from": {
            "name": "Tom Brady", "id": "X12"
         },
         "message": "Looking forward to 2010!",
         "actions": [
            {
               "name": "Comment",
               "link": "http://www.facebook.com/X999/posts/Y999"
            },
            {
               "name": "Like",
               "link": "http://www.facebook.com/X999/posts/Y999"
            }
         ],
         "type": "status",
         "created_time": "2010-08-02T21:27:44+0000",
         "updated_time": "2010-08-02T21:27:44+0000"
      },
      {
         "id": "X998_Y998",
         "from": {
            "name": "Peyton Manning", "id": "X18"
         },
         "message": "Where's my contract?",
         "actions": [
            {
               "name": "Comment",
               "link": "http://www.facebook.com/X998/posts/Y998"
            },
            {
               "name": "Like",
               "link": "http://www.facebook.com/X998/posts/Y998"
            }
         ],
         "type": "status",
         "created_time": "2010-08-02T21:27:44+0000",
         "updated_time": "2010-08-02T21:27:44+0000"
      }
   ]
}
```

The table we want to analyze is represented by the array value of the “data” object. Here is how this is specified in the create table statement:

From Connect 1.07.0002:

```
CREATE TABLE jfacebook (
`ID` CHAR(10) jpath='id',
`Name` CHAR(32) jpath='from.name',
`MyID` CHAR(16) jpath='from.id',
`Message` VARCHAR(256) jpath='message',
`Action` CHAR(16) jpath='actions..name',
`Link` VARCHAR(256) jpath='actions..link',
`Type` CHAR(16) jpath='type',
`Created` DATETIME date_format='YYYY-MM-DD\'T\'hh:mm:ss' jpath='created_time',
`Updated` DATETIME date_format='YYYY-MM-DD\'T\'hh:mm:ss' jpath='updated_time')
ENGINE=CONNECT table_type=JSON file_name='facebook.json' option_list='Object=data,Expand=actions';
```

From Connect 1.6:

```
CREATE TABLE jfacebook (
`ID` CHAR(10) field_format='id',
`Name` CHAR(32) field_format='from.name',
`MyID` CHAR(16) field_format='from.id',
`Message` VARCHAR(256) field_format='message',
`Action` CHAR(16) field_format='actions..name',
`Link` VARCHAR(256) field_format='actions..link',
`Type` CHAR(16) field_format='type',
`Created` DATETIME date_format='YYYY-MM-DD\'T\'hh:mm:ss' field_format='created_time',
`Updated` DATETIME date_format='YYYY-MM-DD\'T\'hh:mm:ss' field_format='updated_time')
ENGINE=CONNECT table_type=JSON file_name='facebook.json' option_list='Object=data,Expand=actions';
```

Until Connect 1.5:

```
CREATE TABLE jfacebook (
`ID` CHAR(10) field_format='id',
`Name` CHAR(32) field_format='from:name',
`MyID` CHAR(16) field_format='from:id',
`Message` VARCHAR(256) field_format='message',
`Action` CHAR(16) field_format='actions::name',
`Link` VARCHAR(256) field_format='actions::link',
`Type` CHAR(16) field_format='type',
`Created` DATETIME date_format='YYYY-MM-DD\'T\'hh:mm:ss' field_format='created_time',
`Updated` DATETIME date_format='YYYY-MM-DD\'T\'hh:mm:ss' field_format='updated_time')
ENGINE=CONNECT table_type=JSON file_name='facebook.json' option_list='Object=data,Expand=actions';
```

This is the object option that gives the Jpath of the table. Note also an alternate way to declare the array to be expanded by the expand option of the option_list.

Because some string values contain a date representation, the corresponding columns are declared as datetime and the date format is specified for them.

The Jpath of the object option has the same syntax as the column Jpath but of course all array steps must be specified using the [n] (until Connect 1.5) or n (from Connect 1.6) format.

Note: This applies to the whole document for tables having `PRETTY = 2` (see below). Otherwise, it applies to the document objects of each file records.

JSON File Formats

The examples we have seen so far are files that, even they can be formatted in different ways (blanks, tabs, carriage return and line feed are ignored when parsing them), respect the JSON syntax and are made of only one item (Object or Array). Like for XML files, they are entirely parsed and a memory representation is made used to process them. This implies that they are of reasonable size to avoid an out of memory condition. Tables based on such files are recognized by the option Pretty=2 that we did not specify above because this is the default.

An alternate format, which is the format of exported MongoDB files, is a file where each row is physically stored in one file record. For instance:

```
{ "_id" : "01001", "city" : "AGAWAM", "loc" : [ -72.622739, 42.070206 ], "pop" : 15338, "state" : "MA" }
{ "_id" : "01002", "city" : "CUSHMAN", "loc" : [ -72.51564999999999, 42.377017 ], "pop" : 36963, "state"
: "MA" }
{ "_id" : "01005", "city" : "BARRE", "loc" : [ -72.1083540000001, 42.409698 ], "pop" : 4546, "state" :
"MA" }
{ "_id" : "01007", "city" : "BELCHERTOWN", "loc" : [ -72.4109530000001, 42.275103 ], "pop" : 10579,
"state" : "MA" }
…
{ "_id" : "99929", "city" : "WRANGELL", "loc" : [ -132.352918, 56.433524 ], "pop" : 2573, "state" : "AK"
}
{ "_id" : "99950", "city" : "KETCHIKAN", "loc" : [ -133.18479, 55.942471 ], "pop" : 422, "state" : "AK" }
```

The original file, “cities.json”, has 29352 records. To base a table on this file we must specify the option Pretty=0 in the option list. For instance:

From Connect 1.07.0002:

```
CREATE TABLE cities (
`_id` CHAR(5) KEY,
`city` CHAR(32),
`lat` DOUBLE(12,6) jpath='loc.0',
`long` DOUBLE(12,6) jpath='loc.1',
`pop` INT(8),
`state` CHAR(2) distrib='clustered')
ENGINE=CONNECT table_type=JSON file_name='cities.json' lrecl=128 option_list='pretty=0';
```

From Connect 1.6:

```
CREATE TABLE cities (
`_id` CHAR(5) KEY,
`city` CHAR(32),
`lat` DOUBLE(12,6) field_format='loc.0',
`long` DOUBLE(12,6) field_format='loc.1',
`pop` INT(8),
`state` CHAR(2) distrib='clustered')
ENGINE=CONNECT table_type=JSON file_name='cities.json' lrecl=128 option_list='pretty=0';
```

Until Connect 1.5:

```
CREATE TABLE cities (
`_id` CHAR(5) KEY,
`city` CHAR(32),
`long` DOUBLE(12,6) field_format='loc:[0]',
`lat` DOUBLE(12,6) field_format='loc:[1]',
`pop` INT(8),
`state` CHAR(2) distrib='clustered')
ENGINE=CONNECT table_type=JSON file_name='cities.json' lrecl=128 option_list='pretty=0';
```

Note the use of [n] (until Connect 1.5) or n (from Connect 1.6) array specifications for the longitude and latitude columns.

When using this format, the table is processed by CONNECT like a DOS, CSV or FMT table. Rows are retrieved and parsed by records and the table can be very large. Another advantage is that such a table can be indexed, which can be of great value for very large tables. The “distrib” option of the “state” column tells CONNECT to use block indexing when possible.

For such tables – as well as for *pretty=1* ones – the record size must be specified using the LRECL option. Be sure you don’t specify it too small as it is used to allocate the read/write buffers and the memory used for parsing the rows. If in doubt, be generous as it does not cost much in memory allocation.

Another format exists, noted by Pretty=1, which is similar to this one but has some additions to represent a JSON array. A header and a trailer records are added containing the opening and closing square bracket, and all records but the last are followed by a comma. It has the same advantages for reading and updating, but inserting and deleting are executed in the pretty=2 way.

Alternate Table Arrangement

We have seen that the most natural way to represent a table in a JSON file is to make it on an array of objects. However, other possibilities exist. A table can be an array of arrays, a one column table can be an array of values, or a one row table can be just one object or one value. Single row tables are internally handled by adding a one value array around them.

Let us see how to handle, for instance, a table that is an array of arrays. The file:

```
[
  [56, "Coucou", 500.00],
  [[2,0,1,4], "Hello World", 2.0316],
  ["1784", "John Doo", 32.4500],
  [1914, ["Nabucho","donosor"], 5.12],
  [7, "sept", [0.77,1.22,2.01]],
  [8, "huit", 13.0]
]
```

A table can be created on this file as:

From Connect 1.07.0002:

```
CREATE TABLE xjson (
`a` INT(6) jpath='1',
`b` CHAR(32) jpath='2',
`c` DOUBLE(10,4) jpath='3')
ENGINE=CONNECT table_type=JSON file_name='test.json' option_list='Pretty=1,Jmode=1,Base=1' lrecl=128;
```

From Connect 1.6:

```
CREATE TABLE xjson (
`a` INT(6) field_format='1',
`b` CHAR(32) field_format='2',
`c` DOUBLE(10,4) field_format='3')
ENGINE=CONNECT table_type=JSON file_name='test.json' option_list='Pretty=1,Jmode=1,Base=1' lrecl=128;
```

Until Connect 1.5:

```
CREATE TABLE xjson (
`a` INT(6) field_format='[1]',
`b` CHAR(32) field_format='[2]',
`c` DOUBLE(10,4) field_format='[3]')
ENGINE=CONNECT table_type=JSON file_name='test.json'
option_list='Pretty=1,Jmode=1,Base=1' lrecl=128;
```

Columns are specified by their position in the row arrays. By default, this is zero-based but for this table the base was set to 1 by the *Base* option of the option list. Another new option in the option list is Jmode=1.
It indicates what type of table this is. The Jmode values are:

1. An array of objects. This is the default.
2. An array of Array. Like this one.
3. An array of values.

When reading, this is not required as the type of the array items is specified for the columns; however, it is required when inserting new rows so CONNECT knows what to insert. For instance:

```
INSERT INTO xjson VALUES(25, 'Breakfast', 1.414);
```

After this, it is displayed as:

a	b	c
56	Coucou	500.0000
2	Hello World	2.0316
1784	John Doo	32.4500
1914	Nabucho	5.1200
7	sept	0.7700
8	huit	13.0000

a	b	c
25	Breakfast	1.4140

Unspecified array values are represented by their first element.

Getting and Setting JSON Representation of a Column

We have seen that columns corresponding to a Json object or array are retrieved by default as the concatenation of all its values separated by a blank. It is also possible to retrieve and display such column contains as the full JSON string corresponding to it in the JSON file. This is specified in the JPATH by a "*" where the object or array would be specified.

Note: When having columns generated by discovery, this can be specified by adding the STRINGIFY option to ON or 1 in the option list.

For instance:

From Connect 1.07.0002:

```
CREATE TABLE jsample2 (
ISBN CHAR(15),
Lng CHAR(2) jpath='LANG',
json_Author CHAR(255) jpath='AUTHOR.*',
Title CHAR(32) jpath='TITLE',
YEAR INT(4) jpath='DATEPUB')
ENGINE=CONNECT table_type=JSON file_name='biblio3.json';
```

From Connect 1.6:

```
CREATE TABLE jsample2 (
ISBN CHAR(15),
Lng CHAR(2) field_format='LANG',
json_Author CHAR(255) field_format='AUTHOR.*',
Title CHAR(32) field_format='TITLE',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON file_name='biblio3.json';
```

Until Connect 1.5:

```
CREATE TABLE jsample2 (
ISBN CHAR(15),
Lng CHAR(2) field_format='LANG',
json_Author CHAR(255) field_format='AUTHOR:*',
Title CHAR(32) field_format='TITLE',
YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON file_name='biblio3.json';
```

Now the query:

```
SELECT json_Author FROM jsample2;
```

will return and display :

json_Author
[{"FIRSTNAME":"Jean-Christophe","LASTNAME":"Bernadac"},{"FIRSTNAME":"François","LASTNAME":"Knab"}]
[{"FIRSTNAME":"William J.","LASTNAME":"Pardi"}]

Note: Prefixing the column name by *json_* is optional but is useful when using the column as argument to Connect UDF functions, making it to be surely recognized as valid Json without aliasing.

This also works on input, a column specified so that it can be directly set to a valid JSON string.

This feature is of great value as we will see below.

Create, Read, Update and Delete Operations on JSON Tables

The SQL commands INSERT, UPDATE and DELETE are fully supported for JSON tables except those returned by REST queries. For INSERT and UPDATE, if the target values are simple values, there are no problems.

However, there are some issues when the added or modified values are objects or arrays.

Concerning objects, the same problems exist that we have already seen with the XML type. The added or modified object will have the format described in the table definition, which can be different from the one of the JSON file. Modifications should be done using a file specifying the full path of modified objects.

New problems are raised when trying to modify the values of an array. Only updates can be done on the original table. First of all, for the values of the array to be distinct values, all update operations concerning array values must be done using a table expanding this array.

For instance, to modify the authors of the `biblio.json` based table, the `jsampex` table must be used. Doing so, updating and deleting authors is possible using standard SQL commands. For example, to change the first name of Knab from François to John:

```
UPDATE jsampex SET authorfn = 'John' WHERE authorln = 'Knab';
```

However It would be wrong to do:

```
UPDATE jsampex SET authorfn = 'John' WHERE isbn = '9782212090819';
```

Because this would change the first name of both authors as they share the same ISBN.

Where things become more difficult is when trying to delete or insert an author of a book. Indeed, a delete command will delete the whole book and an insert command will add a new complete row instead of adding a new author in the same array. Here we are penalized by the SQL language that cannot give us a way to specify this. Something like:

```
UPDATE jsampex ADD authorfn = 'Charles', authorln = 'Dickens'
WHERE title = 'XML en Action';
```

However this does not exist in SQL. Does this mean that it is impossible to do it? No, but it requires us to use a table specified on the same file but adapted to this task. One way to do it is to specify a table for which the authors are no more an expanded array. Supposing we want to add an author to the “XML en Action” book. We will do it on a table containing just the author(s) of that book, which is the second book of the table.

From Connect 1.6:

```
CREATE TABLE jauthor (
FIRSTNAME CHAR(64),
LASTNAME CHAR(64))
ENGINE=CONNECT table_type=JSON File_name='biblio3.json' option_list='Object=1.AUTHOR';
```

Until Connect 1.5

```
CREATE TABLE jauthor (
FIRSTNAME CHAR(64),
LASTNAME CHAR(64))
ENGINE=CONNECT table_type=JSON File_name='biblio3.json' option_list='Object=[1]:AUTHOR';
```

The command:

```
SELECT * FROM jauthor;
```

replies:

FIRSTNAME	LASTNAME
William J.	Pardi

It is a standard JSON table that is an array of objects in which we can freely insert or delete rows.

```
INSERT INTO jauthor VALUES('Charles','Dickens');
```

We can check that this was done correctly by:

```
SELECT * FROM jsampex;
```

This will display:

ISBN	Title	AuthorFN	AuthorLN	Year
9782212090819	Construire une application XML	Jean-Christophe	Bernadac	1999
9782212090819	Construire une application XML	John	Knab	1999
9782840825685	XML en Action	William J.	Pardi	1999
9782840825685	XML en Action	Charles	Dickens	1999

Note: If this table were a big table with many books, it would be difficult to know what the order of a specific book is in the table. This can be found by adding a special ROWID column in the table.

However, an alternate way to do it is by using direct JSON column representation as in the `JSAMPLE2` table. This can be done by:

```
UPDATE jsample2 SET json_Author =
'[{"FIRSTNAME":"William J.","LASTNAME":"Pardi"},
  {"FIRSTNAME":"Charles","LASTNAME":"Dickens"}]'
WHERE isbn = '9782840825685';
```

Here, we didn't have to find the index of the sub array to modify. However, this is not quite satisfying because we had to manually write the whole JSON value to set to the json_Author column.

Therefore we need specific functions to do so. They are introduced now.

JSON User Defined Functions

Although such functions written by other parties do exist,[2] CONNECT provides its own UDFs that are specifically adapted to the JSON table type and easily available because, being inside the CONNECT library or DLL, they require no additional module to be loaded (see CONNECT - Compiling JSON UDFs in a Separate Library to make these functions in a separate library module).

Here is the list of the CONNECT functions; more can be added if required.

Name	Type	Return	Description	Added
jbin_array	Function	STRING*	Make a JSON array containing its arguments.	MariaDB 10.1.9
jbin_array_add	Function	STRING*	Adds to its first array argument its second arguments.	MariaDB 10.1.9

Name	Type	Return	Description	Added
jbin_array_add_values	Function	STRING*	Adds to its first array argument all following arguments.	
jbin_array_delete	Function	STRING*	Deletes the nth element of its first array argument.	MariaDB 10.1.9
jbin_file	Function	STRING*	Returns of a (json) file contain.	MariaDB 10.1.9
jbin_get_item	Function	STRING*	Access and returns a json item by a JPATH key.	MariaDB 10.1.9
jbin_insert_item	Function	STRING	Insert item values located to paths.	
jbin_item_merge	Function	STRING*	Merges two arrays or two objects.	MariaDB 10.1.9
jbin_object	Function	STRING*	Make a JSON object containing its arguments.	MariaDB 10.1.9
jbin_object_nonull	Function	STRING*	Make a JSON object containing its not null arguments.	MariaDB 10.1.9
jbin_object_add	Function	STRING*	Adds to its first object argument its second argument.	MariaDB 10.1.9
jbin_object_delete	Function	STRING*	Deletes the nth element of its first object argument.	MariaDB 10.1.9
jbin_object_key	Function	STRING*	Make a JSON object for key/value pairs.	
jbin_object_list	Function	STRING*	Returns the list of object keys as an array.	MariaDB 10.1.9
jbin_set_item	Function	STRING	Set item values located to paths.	
jbin_update_item	Function	STRING	Update item values located to paths.	
jfile_bjson	Function	STRING	Convert a pretty=0 file to another BJson file.	MariaDB 10.5.9, MariaDB 10.4.18, MariaDB 10.3.28, MariaDB 10.2.36
jfile_convert	Function	STRING	Convert a Json file to another pretty=0 file.	MariaDB 10.5.9, MariaDB 10.4.18, MariaDB 10.3.28, MariaDB 10.2.36
jfile_make	Function	STRING	Make a json file from its json item first argument.	MariaDB 10.1.9
json_array	Function	STRING	Make a JSON array containing its arguments.	MariaDB 10.0.17 until Connect 1.5
json_array_add	Function	STRING	Adds to its first array argument its second arguments (before MariaDB 10.1.9, all following arguments).	
json_array_add_values	Function	STRING	Adds to its first array argument all following arguments.	MariaDB 10.1.9
json_array_delete	Function	STRING	Deletes the nth element of its first array argument.	
json_array_grp	Aggregate	STRING	Makes JSON arrays from coming argument.	
json_file	Function	STRING	Returns the contains of (json) file.	MariaDB 10.1.9

Name	Type	Return	Description	Added
json_get_item	Function	STRING	Access and returns a json item by a JPATH key.	MariaDB 10.1.9
json_insert_item	Function	STRING	Insert item values located to paths.	
json_item_merge	Function	STRING	Merges two arrays or two objects.	MariaDB 10.1.9
json_locate_all	Function	STRING	Returns the JPATH's of all occurrences of an element.	MariaDB 10.1.9
json_make_array	Function	STRING	Make a JSON array containing its arguments.	From Connect 1.6
json_make_object	Function	STRING	Make a JSON object containing its arguments.	From Connect 1.6
json_object	Function	STRING	Make a JSON object containing its arguments.	MariaDB 10.0.17 until Connect 1.5
json_object_delete	Function	STRING	Deletes the nth element of its first object argument.	MariaDB 10.1.9
json_object_grp	Aggregate	STRING	Makes JSON objects from coming arguments.	
json_object_list	Function	STRING	Returns the list of object keys as an array.	MariaDB 10.1.9
json_object_nonull	Function	STRING	Make a JSON object containing its not null arguments.	
json_serialize	Function	STRING	Serializes the return of a "Jbin" function.	MariaDB 10.1.9
json_set_item	Function	STRING	Set item values located to paths.	
json_update_item	Function	STRING	Update item values located to paths.	
jsonvalue	Function	STRING	Make a JSON value from its unique argument. Called json_value until MariaDB 10.0.22 and MariaDB 10.1.8.	MariaDB 10.0.17
jsoncontains	Function	INTEGER	Returns 0 or 1 if an element is contained in the document.	
jsoncontains_path	Function	INTEGER	Returns 0 or 1 if a JPATH is contained in the document.	
jsonget_string	Function	STRING	Access and returns a string element by a JPATH key.	MariaDB 10.1.9
jsonget_int	Function	INTEGER	Access and returns an integer element by a JPATH key.	MariaDB 10.1.9
jsonget_real	Function	REAL	Access and returns a real element by a JPATH key.	MariaDB 10.1.9
jsonlocate	Function	STRING	Returns the JPATH to access one element.	MariaDB 10.1.9

String values are mapped to JSON strings. These strings are automatically escaped to conform to the JSON syntax. The automatic escaping is bypassed when the value has an alias beginning with 'json_'. This is automatically the case when a JSON UDF argument is another JSON UDF whose name begins with "json_" (not case sensitive). This is why all functions that do not return a Json item are not prefixed by "json_".

Argument string values, for some functions, can alternatively be json file names. When this is ambiguous, alias them as *jfile_*. Full path should be used because UDF functions has no means to know what the current database is. Apparently, when the file name path is not full, it is based on the MariaDB data directory but I am not sure it is always true.

Numeric values are (big) integers, double floating point values or decimal values. Decimal values are character strings containing a numeric representation and are treated as strings. Floating point values contain a decimal point and/or an exponent. Integers are written without decimal points.

To install these functions execute the following commands :[3]

Note

Json function names are often written on this page with leading upper case letters for clarity. It is possible to do so in SQL queries because function names are case insensitive. However, when creating or dropping them, their names must match the case they are in the library module, which is in lower case.

On Unix systems (from Connect 1.7.02):

```
CREATE FUNCTION jsonvalue RETURNS STRING soname 'ha_connect.so';
CREATE FUNCTION json_make_array RETURNS STRING soname 'ha_connect.so';
CREATE FUNCTION json_array_add_values RETURNS STRING soname 'ha_connect.so';

```

Jfile_Bjson

MariaDB starting with 10.5.9

JFile_Bjson was introduced in MariaDB.

```
Jfile_Bjson(in_file_name, out_file_name, lrecl)
```

Converts the first argument pretty=0 json file to Bjson file. B(inary)json is a pre-parsed json format. It is described below in the Performance chapter (available in next Connect versions).

Jfile_Convert

MariaDB starting with 10.5.9

JFile_Convert was introduced in MariaDB.

```
Jfile_Convert(in_file_name, out_file_name, lrecl)
```

Converts the first argument json file to another *pretty=0* json file. The third integer argument is the record length to use. This is often required to process huge json files that would be very slow if they were in *pretty=2* format.

This is done without completely parsing the file, is very fast and requires no big memory.

Jfile_Make

Jfile_Make was added in CONNECT 1.4

```
Jfile_Make(arg1, arg2, [arg3], …)
```

The first argument must be a json item (if it is just a string, Jfile_Make will try its best to see if it is a json item or an input file name). The following arguments are a string file name and an integer pretty value (defaulting to 2) in any order. This function creates a json file containing the first argument item.

The returned string value is the created file name. If not specified as an argument, the file name can in some cases be retrieved from the first argument; in such cases the file itself is modified.

This function can be used to create or format a json file. For instance, supposing we want to format the file tb.json, this can be done with the query:

```
SELECT Jfile_Make('tb.json' jfile_, 2);
```

The tb.json file are changed to:

```
[
  {
    "_id": 5,
    "type": "food",
    "ratings": [
      5,
      8,
      9
    ]
  },
  {
    "_id": 6,
    "type": "car",
    "ratings": [
      5,
      9
    ]
  }
]
```

Json_Array_Add

```
Json_Array_Add(arg1, arg2, [arg3][, arg4][, ...])
```

Note: The following describes this function for CONNECT version 1.4 only. The first argument must be a JSON array. The second argument is added as member of this array:

```
SELECT Json_Array_Add(Json_Array(56,3.1416,'machin',NULL),
'One more') ARRAY;
```

Array
[56,3.141600,“machin”,null,“One more”]

Note: The first array is not escaped, its (alias) name beginning with ‘json_’.

Now we can see how adding an author to the JSAMPLE2 table can alternatively be done:

```
UPDATE jsample2 SET
  json_author = json_array_add(json_author, json_object('Charles' FIRSTNAME, 'Dickens' LASTNAME))
  WHERE isbn = '9782840825685';
```

Note: Calling a column returning JSON a name prefixed by json_ (like json_author here) is good practice and removes the need to give it an alias to prevent escaping when used as an argument.

Additional arguments:
If a third integer argument is given, it specifies the position (zero based) of the added value:

```
SELECT Json_Array_Add('[5,3,8,7,9]' json_, 4, 2) ARRAY;
```

Array
[5,3,4,8,7,9]

If a string argument is added, it specifies the Json path to the array to be modified. For instance:

```
SELECT Json_Array_Add('{"a":1,"b":2,"c":[3,4]}' json_, 5, 1, 'c');
```

Json_Array_Add('{"a":1,"b":2,"c":[3, 4]}' json_, 5, 1, 'c')
{"a":1,"b":2,"c":[3,5,4]}

Json_Array_Add_Values

Json_Array_Add_Values added in CONNECT 1.4 replaces the function Json_Array_Add of CONNECT version 1.3.

```
Json_Array_Add_Values(arg, arglist)
```

The first argument must be a JSON array string. Then all other arguments are added as members of this array:

```
SELECT Json_Array_Add_Values
  (Json_Array(56, 3.1416, 'machin', NULL), 'One more', 'Two more') ARRAY;
```

Array
[56,3.141600,"machin",null,"One more","Two more"]

Json_Array_Delete

```
Json_Array_Delete(arg1, arg2 [,arg3] [...])
```

The first argument should be a JSON array. The second argument is an integer indicating the rank (0 based conforming to general json usage) of the element to delete:

```
SELECT Json_Array_Delete(Json_Array(56,3.1416,'foo',NULL),1) ARRAY;
```

Array
[56,"foo",null]

Now we can see how to delete the second author from the JSAMPLE2 table:

```
UPDATE jsample2 SET json_author = json_array_delete(json_author, 1)
  WHERE isbn = '9782840825685';
```

A Json path can be specified as a third string argument

Json_Array_Grp

```
Json_Array_Grp(arg)
```

This is an aggregate function that makes an array filled from values coming from the rows retrieved by a query. Let us suppose we have the pet table:

name	race	number
John	dog	2
Bill	cat	1
Mary	dog	1
Mary	cat	1
Lisbeth	rabbit	2
Kevin	cat	2
Kevin	bird	6
Donald	dog	1
Donald	fish	3

The query:

```
SELECT name, json_array_grp(race) FROM pet GROUP BY name;
```

will return:

name
Bill
Donald
John
Kevin
Lisbeth
Mary

One problem with the JSON aggregate functions is that they construct their result in memory and cannot know the needed amount of storage, not knowing the number of rows of the used table.

Therefore, the number of values for each group is limited. This limit is the value of JsonGrpSize whose default value is 10 but can be set using the JsonSet_Grp_Size function. Nevertheless, working on a larger table is possible, but only after setting JsonGrpSize to the ceiling of the number of rows per group for the table. Try not to set it to a very large value to avoid memory exhaustion.

JsonContains

```
JsonContains(json_doc, item [, int])<
```

This function can be used to check whether an item is contained in a document. Its arguments are the same than the ones of the JsonLocate function; only the return value changes. The integer returned value is 1 is the item is contained in the document or 0 otherwise.

JsonContains_Path

```
JsonContains_Path(json_doc, path)
```

This function can be used to check whether a Json path is contained in the document. The integer returned value is 1 is the path is contained in the document or 0 otherwise.

Json_File

```
Json_File(arg1, [arg2, [arg3]], …)
```

The first argument must be a file name. This function returns the text of the file that is supposed to be a json file. If only one argument is specified, the file text is returned without being parsed. Up to two additional arguments can be specified:

A string argument is the path to the sub-item to be returned. An integer argument specifies the pretty format value of the file.

This function is chiefly used to get the json item argument of other json functions from a json file. For instance, supposing the file tb.json is:

```
{ "_id" : 5, "type" : "food", "ratings" : [ 5, 8, 9 ] }
{ "_id" : 6, "type" : "car", "ratings" : [ 5, 9 ] }
```

Extracting a value from it can be done with a query such as:

```
SELECT JsonGet_String(Json_File('tb.json', 0), '$[1].type') "Type";
```

This query returns:

Type
car

However, we'll see that, most of the time, it is better to use Jbin_File or to directly specify the file name in queries. In particular this function should not be used for queries that must modify the json item because, even if the modified json is returned, the file itself would be unchanged.

Json_Get_Item

Json_Get_Item was added in CONNECT 1.4.

```
Json_Get_Item(arg1, arg2, …)
```

This function returns a subset of the json document passed as first argument. The second argument is the json path of the item to be returned and should be one returning a json item (terminated by a '*'). If not, the function will try to make it right but this is not foolproof. For instance:

```
SELECT Json_Get_Item(Json_Object('foo' AS "first", Json_Array('a', 33)
  AS "json_second"), 'second') AS "item";
```

The correct path should have been 'second.*'), but in this simple case the function was able to make it right. The returned item:

item
["a",33]

Note: The array is aliased “json_second” to indicate it is a json item and avoid escaping it. However, the “json_” prefix is skipped when making the object and must not be added to the path.

JsonGet_Grp_Size

```
JsonGet_Grp_Size(val)
```

This function returns the JsonGrpSize value.

JsonGet_String / JsonGet_Int / JsonGet_Real

JsonGet_String, JsonGet_Int and JsonGet_Real were added in CONNECT 1.4.

```
JsonGet_String(arg1, arg2, [arg3] …)
JsonGet_Int(arg1, arg2, [arg3] …)
JsonGet_Real(arg1, arg2, [arg3] …)
```

The first argument should be a JSON item. If it is a string with no alias, it are converted as a json item. The second argument is the path of the item to be located in the first argument and returned, eventually converted according to the used function:

```
SELECT
JsonGet_String('{"qty":7,"price":29.50,"garanty":null}','price') "String",
JsonGet_Int('{"qty":7,"price":29.50,"garanty":null}','price') "Int",
JsonGet_Real('{"qty":7,"price":29.50,"garanty":null}','price') "Real";
```

This query returns:

String	Int	Real
29.50	29	29.500000000000000

The function *JsonGet_Real* can be given a third argument to specify the number of decimal digits of the returned value. For instance:

```
SELECT
JsonGet_Real('{"qty":7,"price":29.50,"garanty":null}','price',4) "Real";
```

This query returns:

String
29.50

The given path can specify all operators for arrays except the “expand” [*] operator). For instance:

```
SELECT
JsonGet_Int(Json_Array(45,28,36,45,89), '[4]') "Rank",
JsonGet_Int(Json_Array(45,28,36,45,89), '[#]') "Number",
JsonGet_String(Json_Array(45,28,36,45,89), '[","]') "Concat",
JsonGet_Int(Json_Array(45,28,36,45,89), '[+]') "Sum",
JsonGet_Real(Json_Array(45,28,36,45,89), '[!]', 2) "Avg";
```

The result:

Rank	Number	Concat	Sum	Avg
89	5	45,28,36,45,89	243	48.60

Json_Item_Merge

```
Json_Item_Merge(arg1, arg2, …)
```

This function merges two arrays or two objects. For arrays, this is done by adding to the first array all the values of the second array. For instance:

```
SELECT Json_Item_Merge(Json_Array('a','b','c'), Json_Array('d','e','f')) AS "Result";
```

The function returns:

Result
[“a”,“b”,“c”,“d”,“e”,“f”]

For objects, the pairs of the second object are added to the first object if the key does not yet exist in it; otherwise the pair of the first object is set with the value of the matching pair of the second object. For instance:

```
SELECT Json_Item_Merge(Json_Object(1 "a", 2 "b", 3 "c"), Json_Object(4 "d",5 "b",6 "f"))
  AS "Result";
```

The function returns:

Result
{“a”:1,“b”:5,“c”:3,“d”:4,“f”:6}

JsonLocate

```
JsonLocate(arg1, arg2, [arg3], …):
```

The first argument must be a JSON tree. The second argument is the item to be located. The item to be located can be a constant or a json item. Constant values must be equal in type and value to be found. This is “shallow equality” – strings, integers and doubles won’t match.

This function returns the json path to the located item or null if it is not found:

```
SELECT JsonLocate('{"AUTHORS":[{"FN":"Jules", "LN":"Verne"},
  {"FN":"Jack", "LN":"London"}]}' json_, 'Jack') PATH;
```

This query returns:

Path
$.AUTHORS[1].FN

The path syntax is the same used in JSON CONNECT tables.

By default, the path of the first occurrence of the item is returned. The third parameter can be used to specify the occurrence whose path is to be returned. For instance:

```
SELECT
JsonLocate('[45,28,[36,45],89]',45) FIRST,
JsonLocate('[45,28,[36,45],89]',45,2) SECOND,
JsonLocate('[45,28,[36,45],89]',45.0) `wrong type`,
JsonLocate('[45,28,[36,45],89]','[36,45]' json_) JSON;
```

first	second	wrong type	json
$[0]	$[2][1]		$[2]

For string items, the comparison is case sensitive by default. However, it is possible to specify a string to be compared case insensitively by giving it an alias beginning by “ci”:

```
SELECT JsonLocate('{"AUTHORS":[{"FN":"Jules", "LN":"Verne"},
  {"FN":"Jack", "LN":"London"}]}' json_, 'VERNE' ci) PATH;
```

Path
$.AUTHORS[0].LN

Json_Locate_All

```
Json_Locate_All(arg1, arg2, [arg3], …):
```

The first argument must be a JSON item. The second argument is the item to be located. This function returns the paths to all locations of the item as an array of strings:

```
SELECT Json_Locate_All('[[45,28],[[36,45],89]]',45);
```

This query returns:

All paths
[“$[0][0]”,“$[1][0][1]”]

The returned array can be applied other functions. For instance, to get the number of occurrences of an item in a json tree, you can do:

```
SELECT JsonGet_Int(Json_Locate_All('[[45,28],[[36,45],89]]',45), '$[#]') "Nb of occurs";
```

The displayed result:

Nb of occurs
2

If specified, the third integer argument set the depth to search in the document. This means the maximum items in the paths. This value defaults to 10 but can be increased for complex documents or reduced to set the maximum wanted depth of the returned paths.

Json_Make_Array

```
Json_Make_Array(val1, …, valn)
```

Json_Make_Array returns a string denoting a JSON array with all its arguments as members:

```
SELECT Json_Make_Array(56, 3.1416, 'My name is "Foo"', NULL);
```

Json_Make_Array(56, 3.1416, ‘My name is “Foo”’,N ULL)
[56,3.141600,“My name is”Foo”“,null]

Note: The argument list can be void. If so, a void array is returned.

Json_Make_Object

```
Json_Make_Object(arg1, …, argn)
```

Json_Make_Object returns a string denoting a JSON object. For instance:

```
SELECT Json_Make_Object(56, 3.1416, 'machin', NULL);
```

The object is filled with pairs corresponding to the given arguments. The key of each pair is made from the argument (default or specified) alias.

Json_Make_Object(56, 3.1416, 'machin', NULL)
{"56":56,"3.1416":3.141600,"machin":"machin","NULL":null}

When needed, it is possible to specify the keys by giving an alias to the arguments:

```
SELECT Json_Make_Object(56 qty, 3.1416 price, 'machin' truc, NULL garanty);
```

Json_Make_Object(56 qty,3.1416 price,'machin' truc, NULL garanty)
{"qty":56,"price":3.141600,"truc":"machin","garanty":null}

If the alias is prefixed by 'json_' (to prevent escaping) the key name is stripped from that prefix.

This function is chiefly useful when entering values retrieved from a table, the key being by default the column name:

```
SELECT Json_Make_Object(matricule, nom, titre, salaire) FROM connect.employe WHERE nom = 'PANTIER';
```

Json_Make_Object(matricule, nom, titre, salaire)
{"matricule":40567,"nom":"PANTIER","titre":"DIRECTEUR","salaire":14000.000000}

Json_Object_Add

```
Json_Object_Add(arg1, arg2, [arg3] …)
```

The first argument must be a JSON object. The second argument is added as a pair to this object:

```
SELECT Json_Object_Add
  ('{"item":"T-shirt","qty":27,"price":24.99}' json_old,'blue' color) newobj;
```

newobj
{"item":"T-shirt","qty":27,"price":24.990000,"color":"blue"}

Note: If the specified key already exists in the object, its value is replaced by the new one.

The third string argument is a Json path to the target object.

Json_Object_Delete

```
Json_Object_Delete(arg1, arg2, [arg3] …):
```

The first argument must be a JSON object. The second argument is the key of the pair to delete:

```
SELECT Json_Object_Delete('{"item":"T-shirt","qty":27,"price":24.99}' json_old, 'qty') newobj;
```

newobj
{"item":"T-shirt","price":24.99}

The third string argument is a Json path to the object to be the target of deletion.

Json_Object_Grp

```
Json_Object_Grp(arg1,arg2)
```

This function works like Json_Array_Grp. It makes a JSON object filled with value pairs whose keys are passed from its first argument and values are passed from its second argument.

This can be seen with the query:

```
SELECT name, json_object_grp(NUMBER,race) FROM pet GROUP BY name;
```

This query returns:

name	json_object_grp(number,race)
Bill	{“cat”:1}
Donald	{“dog”:1,“fish”:3}
John	{“dog”:2}
Kevin	{“cat”:2,“bird”:6}
Lisbeth	{“rabbit”:2}
Mary	{“dog”:1,“cat”:1}

Json_Object_Key

```
Json_Object_Key([key1, val1 [, …, keyn, valn]])
```

Return a string denoting a JSON object. For instance:

```
SELECT Json_Object_Key('qty', 56, 'price', 3.1416, 'truc', 'machin', 'garanty', NULL);
```

The object is filled with pairs made from each key/value arguments.

Json_Object_Key(‘qty’, 56, ‘price’, 3.1416, ‘truc’, ‘machin’, ‘garanty’, NULL)
{“qty”:56,“price”:3.141600,“truc”:“machin”,“garanty”:null}

Json_Object_List

```
Json_Object_List(arg1, …):
```

The first argument must be a JSON object. This function returns an array containing the list of all keys existing in the object:

```
SELECT Json_Object_List(Json_Object(56 qty,3.1416 price,'machin' truc, NULL garanty))
  "Key List";
```

Key List
[“qty”,“price”,“truc”,“garanty”]

Json_Object_Nonull

```
Json_Object_Nonull(arg1, …, argn)
```

This function works like Json_Make_Object but “null” arguments are ignored and not inserted in the object. Arguments are regarded as “null” if they are JSON null values, void arrays or objects, or arrays or objects containing

only null members.

It is mainly used to avoid constructing useless null items when converting tables (see later).

Json_Object_Values

```
Json_Object_Values(json_object)
```

The first argument must be a JSON object. This function returns an array containing the list of all values existing in the object:

```
SELECT Json_Object_Values('{"One":1,"Two":2,"Three":3}') "Value List";
```

Value List
[1,2,3]

JsonSet_Grp_Size

```
JsonSet_Grp_Size(val)
```

This function is used to set the JsonGrpSize value. This value is used by the following aggregate functions as a ceiling value of the number of items in each group. It returns the JsonGrpSize value that can be its default value when passed 0 as argument.

Json_Set_Item / Json_Insert_Item / Json_Update_Item

```
Json_{Set | Insert | Update}_Item(json_doc, [item, path [, val, path …]])
```

These functions insert or update data in a JSON document and return the result. The value/path pairs are evaluated left to right. The document produced by evaluating one pair becomes the new value against which the next pair is evaluated.

- Json_Set_Item replaces existing values and adds non-existing values.
- Json_Insert_Item inserts values without replacing existing values.
- Json_Update_Item replaces only existing values.

Example:

```
SET @j = Json_Array(1, 2, 3, Json_Object_Key('quatre', 4));
SELECT Json_Set_Item(@j, 'foo', '$[1]', 5, '$[3].cinq') AS "Set",
Json_Insert_Item(@j, 'foo', '$[1]', 5, '$[3].cinq') AS "Insert",
Json_Update_Item(@j, 'foo', '$[1]', 5, '$[3].cinq') AS "Update";
```

This query returns:

Set	Insert	Update
[1,“foo”,3,{“quatre”:4,“cinq”:5}]	[1,2,3,{“quatre”:4,“cinq”:5}]	[1,“foo”,3,{“quatre”:4}]

JsonValue

```
JsonValue (val)
```

Returns a JSON value as a string, for instance:

```
SELECT JsonValue(3.1416);
```

JsonValue(3.1416)
3.141600

The “JBIN” Return Type

Almost all functions returning a json string - whose name begins with *Json_* - have a counterpart with a name beginning with *Jbin_*. This is both for performance (speed and memory) as well as for better control of what the functions should do.

This is due to the way CONNECT UDFs work internally. The Json functions, when receiving json strings as parameters, parse them and construct a binary tree in memory. They work on this tree and before returning; serialize this tree to return a new json string.

If the json document is large, this can take up a large amount of time and storage space. It is all right when one simple json function is called – it must be done anyway – but is a waste of time and memory when json functions are used as parameters to other json functions.

To avoid multiple serializing and parsing, the Jbin functions should be used as parameters to other functions. Indeed, they do not serialize the memory document tree, but return a structure allowing the receiving function to have direct access to the memory tree. This saves the serialize-parse steps otherwise needed to pass the argument and removes the need to reallocate the memory of the binary tree, which by the way is 6 to 7 times the size of the json string. For instance:

```
SELECT Json_Object(Jbin_Array_Add(Jbin_Array('a','b','c'), 'd') AS "Jbin_foo") AS "Result";
```

This query returns:

Result
{“foo”:[“a”,“b”,“c”,“d”]}

Here the binary json tree allocated by *Jbin_Array* is completed by *Jbin_Array_Add* and *Json_Object* and serialized only once to make the final result string. It would be serialized and parsed two more times if using “Json” functions.

Note that Jbin results are recognized as such because they are aliased beginning with “Jbin_”. This is why in the *Json_Object* function the alias is specified as “Jbin_foo”.

What happens if it is not recognized as such? These functions are declared as returning a string and to take care of this, the returned structure begins with a zero-terminated string. For instance:

```
SELECT Jbin_Array('a','b','c');
```

This query replies:

Jbin_Array(‘a’,‘b’,‘c’)
Binary Json array

Note: When testing, the tree returned by a “Jbin” function can be seen using the *Json_Serialize* function whose unique parameter must be a “Jbin” result. For instance:

```
SELECT Json_Serialize(Jbin_Array('a','b','c'));
```

This query returns:

Json_Serialize(Jbin_Array(‘a’,‘b’,‘c’))
[“a”,“b”,“c”]

Note: For this simple example, this is equivalent to using the *Json_Array* function.

Using a File as JSON UDF First Argument

We have seen that many json UDFs can have an additional argument not yet described. This is in the case where the json item argument was referring to a file. Then the additional integer argument is the pretty value of the json file. It matters only when the first argument is just a file name (to make the UDF understand this argument is a file name, it should be aliased with a name beginning with jfile_) or if the function modifies the file, in which case it are rewritten with this pretty format.

The json item is created by extracting the required part from the file. This can be the whole file but more often only some of it. There are two ways to specify the sub-item of the file to be used:

1. Specifying it in the Json_File or Jbin_File arguments.
2. Specifying it in the receiving function (not possible for all functions).

It doesn't make any difference when the *Jbin_File* is used but it does with *Json_File*. For instance:

```
SELECT Jfile_Make('{"a":1, "b":[44, 55]}' json_, 'test.json');
SELECT Json_Array_Add(Json_File('test.json', 'b'), 66);
```

The second query returns:

Json_Array_Add(Json_File('test.json', 'b'), 66)
[44,55,66]

It just returns the – modified – subset returned by the Json_File function, while the query:

```
SELECT Json_Array_Add(Json_File('test.json'), 66, 'b');
```

returns what was received from *Json_File* with the modification made on the subset.

Json_Array_Add(Json_File('test.json'), 66, 'b')
{"a":1,"b":[44,55,66]}

Note that in both case the test.json file is not modified. This is because the *Json_File* function returns a string representing all or part of the file text but no information about the file name. This is all right to check what would be the effect of the modification to the file.

However, to have the file modified, use the *Jbin_File* function or directly give the file name. *Jbin_File* returns a structure containing the file name, a pointer to the file parsed tree and eventually a pointer to the subset when a path is given as a second argument:

```
SELECT Json_Array_Add(Jbin_File('test.json', 'b'), 66);
```

This query returns:

Json_Array_Add(Jbin_File('test.json', 'b'), 66)
test.json

This time the file is modified. This can be checked with:

```
SELECT Json_File('test.json', 3);
```

Json_File('test.json', 3)
{"a":1,"b":[44,55,66]}

The reason why the first argument is returned by such a query is because of tables such as:

```
CREATE TABLE tb (
n INT KEY,
jfile_cols CHAR(10) NOT NULL);
INSERT INTO tb VALUES(1,'test.json');
```

In this table, the *jfile_cols* column just contains a file name. If we update it by:

```
UPDATE tb SET jfile_cols = SELECT Json_Array_Add(Jbin_File('test.json', 'b'), 66)
WHERE n = 1;
```

This is the test.json file that must be modified, not the jfile_cols column. This can be checked by:

```
SELECT JsonGet_String(jfile_cols, '[1]:*') FROM tb;
```

JsonGet_String(jfile_cols, '[1]:*')
{“a”:1,“b”:[44,55,66]}

Note: It was an important facility to name the second column of the table beginning by “jfile_” so the json functions knew it was a file name without obliging to specify an alias in the queries.

Using “Jbin” to Control the Query Execution

This is applying in particular when acting on json files. We have seen that a file was not modified when using the *Json_File* function as an argument to a modifying function because the modifying function just received a copy of the json file. This is not true when using the *Jbin_File* function that does not serialize the binary document and make it directly accessible. Also, as we have seen earlier, json functions that modify their first file parameter modify the file and return the file name. This is done by directly serializing the internal binary document as a file.

However, the “Jbin” counterpart of these functions does not serialize the binary document and thus does not modify the json file. For example let us compare these two queries:

/* First query */

```
SELECT Json_Object(Jbin_Object_Add(Jbin_File('bt2.json'), 4 AS "d") AS "Jbin_bt1")
  AS "Result";
```

/* Second query */

```
SELECT Json_Object(Json_Object_Add(Jbin_File('bt2.json'), 4 AS "d") AS "Jfile_bt1")
  AS "Result";
```

Both queries return:

Result
{“bt1”:{“a”:1,“b”:2,“c”:3,“d”:4}}

In the first query *Jbin_Object_Add* does not serialize the document (no “Jbin” functions do) and *Json_Object* just returns a serialized modified tree. Consequently, the file bt2.json is not modified. This query is all right to copy a modified version of the json file without modifying it.

However, in the second query *Json_Object_Add* does modify the json file and returns the file name. The *Json_Object* function receives this file name, reads and parses the file, makes an object from it and returns the serialized result. This modification can be done willingly but can be an unwanted side effect of the query.

Therefore, using “Jbin” argument functions, in addition to being faster and using less memory, are also safer when dealing with json files that should not be modified.

Using JSON as Dynamic Columns

The JSON nosql language has all the features to be used as an alternative to dynamic columns. For instance, take the following example of dynamic columns:

```
create table assets (
   item_name varchar(32) primary key, /* A common attribute for all items */
   dynamic_cols  blob  /* Dynamic columns are stored here */
 );

INSERT INTO assets VALUES
   ('MariaDB T-shirt', COLUMN_CREATE('color', 'blue', 'size', 'XL'));

INSERT INTO assets VALUES
   ('Thinkpad Laptop', COLUMN_CREATE('color', 'black', 'price', 500));

SELECT item_name, COLUMN_GET(dynamic_cols, 'color' as char) AS color FROM assets;
+-----------------+-------+
| item_name       | color |
+-----------------+-------+
| MariaDB T-shirt | blue  |
| Thinkpad Laptop | black |
+-----------------+-------+
```

/* Remove a column: */

```
UPDATE assets SET dynamic_cols=COLUMN_DELETE(dynamic_cols, "price")
  WHERE COLUMN_GET(dynamic_cols, 'color' AS CHAR)='black';
```

/* Add a column: */

```
UPDATE assets SET dynamic_cols=COLUMN_ADD(dynamic_cols, 'warranty', '3 years')
   WHERE item_name='Thinkpad Laptop';
```

/* You can also list all columns, or get them together with their values in JSON format: */

```
SELECT item_name, column_list(dynamic_cols) FROM assets;
+-----------------+--------------------------+
| item_name       | column_list(dynamic_cols) |
+-----------------+--------------------------+
| MariaDB T-shirt | `size`,`color`            |
| Thinkpad Laptop | `color`,`warranty`        |
+-----------------+--------------------------+

SELECT item_name, COLUMN_JSON(dynamic_cols) FROM assets;
+-----------------+---------------------------------------+
| item_name       | COLUMN_JSON(dynamic_cols)             |
+-----------------+---------------------------------------+
| MariaDB T-shirt | {"size":"XL","color":"blue"}          |
| Thinkpad Laptop | {"color":"black","warranty":"3 years"} |
+-----------------+---------------------------------------+
```

The same result can be obtained with json columns using the json UDF’s:

/* JSON equivalent */

```
create table jassets (
   item_name varchar(32) primary key, /* A common attribute for all items */
   json_cols varchar(512)  /* Jason columns are stored here */
 );

INSERT INTO jassets VALUES
   ('MariaDB T-shirt', Json_Object('blue' color, 'XL' size));

INSERT INTO jassets VALUES
   ('Thinkpad Laptop', Json_Object('black' color, 500 price));

SELECT item_name, JsonGet_String(json_cols, 'color') AS color FROM jassets;
+-----------------+-------+
| item_name       | color |
+-----------------+-------+
| MariaDB T-shirt | blue  |
| Thinkpad Laptop | black |
+-----------------+-------+
```

/* Remove a column: */

```
UPDATE jassets SET json_cols=Json_Object_Delete(json_cols, 'price')
 WHERE JsonGet_String(json_cols, 'color')='black';
```

/* Add a column */

```
UPDATE jassets SET json_cols=Json_Object_Add(json_cols, '3 years' warranty)
 WHERE item_name='Thinkpad Laptop';
```

/* You can also list all columns, or get them together with their values in JSON format: */

```
SELECT item_name, Json_Object_List(json_cols) FROM jassets;
+-----------------+-----------------------------+
| item_name       | Json_Object_List(json_cols) |
+-----------------+-----------------------------+
| MariaDB T-shirt | ["color","size"]            |
| Thinkpad Laptop | ["color","warranty"]        |
+-----------------+-----------------------------+

SELECT item_name, json_cols FROM jassets;
+-----------------+---------------------------------------+
| item_name       | json_cols                             |
+-----------------+---------------------------------------+
| MariaDB T-shirt | {"color":"blue","size":"XL"}          |
| Thinkpad Laptop | {"color":"black","warranty":"3 years"} |
+-----------------+---------------------------------------+
```

However, using JSON brings features not existing in dynamic columns:

- Use of a language used by many implementation and developers.
- Full support of arrays, currently missing from dynamic columns.
- Access of subpart of json by JPATH that can include calculations on arrays.
- Possible references to json files.

With more experience, additional UDFs can be easily written to support new needs.

New Set of BSON Functions

All these functions have been rewritten using the new JSON handling way and are temporarily available changing the J starting name to B. Then Json_Make_Array new style is called using Bson_Make_Array.
Some, such as Bson_Item_Delete, are new and some fix bugs found in their Json counterpart.

Converting Tables to JSON

The JSON UDF's and the direct Jpath "*" facility are powerful tools to convert table and files to the JSON format. For instance, the file `biblio3.json` we used previously can be obtained by converting the `xsample.xml file`. This can be done like this:

From Connect 1.07.0002

```
CREATE TABLE xj1 (ROW VARCHAR(500) jpath='*') ENGINE=CONNECT table_type=JSON file_name='biblio3.json'
option_list='jmode=2';
```

Before Connect 1.07.0002

```
CREATE TABLE xj1 (ROW VARCHAR(500) field_format='*')
 ENGINE=CONNECT table_type=JSON file_name='biblio3.json' option_list='jmode=2';
```

And then :

```
INSERT INTO xj1
  SELECT json_object_nonull(ISBN, LANGUAGE LANG, SUBJECT,
    json_array_grp(json_object(authorfn FIRSTNAME, authorln LASTNAME)) json_AUTHOR, TITLE,
    json_object(translated PREFIX, json_object(tranfn FIRSTNAME, tranln LASTNAME) json_TRANSLATOR)
    json_TRANSLATED, json_object(publisher NAME, LOCATION PLACE) json_PUBLISHER, DATE DATEPUB)
FROM xsampall2 GROUP BY isbn;
```

The xj1 table rows will directly receive the Json object made by the select statement used in the insert statement and the table file are made as shown (xj1 is pretty=2 by default) Its mode is Jmode=2 because the values inserted are strings even if they denote json objects.

Another way to do this is to create a table describing the file format we want before the `biblio3.json` file existed:

From Connect 1.07.0002

```
CREATE TABLE jsampall3 (
ISBN CHAR(15),
LANGUAGE CHAR(2) jpath='LANG',
SUBJECT CHAR(32),
AUTHORFN CHAR(128) jpath='AUTHOR:[X]:FIRSTNAME',
AUTHORLN CHAR(128) jpath='AUTHOR:[X]:LASTNAME',
TITLE CHAR(32),
TRANSLATED CHAR(32) jpath='TRANSLATOR:PREFIX',
TRANSLATORFN CHAR(128) jpath='TRANSLATOR:FIRSTNAME',
TRANSLATORLN CHAR(128) jpath='TRANSLATOR:LASTNAME',
PUBLISHER CHAR(20) jpath='PUBLISHER:NAME',
LOCATION CHAR(20) jpath='PUBLISHER:PLACE',
DATE INT(4) jpath='DATEPUB')
ENGINE=CONNECT table_type=JSON file_name='biblio3.json';
```

Before Connect 1.07.0002

```
CREATE TABLE jsampall3 (
ISBN CHAR(15),
LANGUAGE CHAR(2) field_format='LANG',
SUBJECT CHAR(32),
AUTHORFN CHAR(128) field_format='AUTHOR:[X]:FIRSTNAME',
AUTHORLN CHAR(128) field_format='AUTHOR:[X]:LASTNAME',
TITLE CHAR(32),
TRANSLATED CHAR(32) field_format='TRANSLATOR:PREFIX',
TRANSLATORFN CHAR(128) field_format='TRANSLATOR:FIRSTNAME',
TRANSLATORLN CHAR(128) field_format='TRANSLATOR:LASTNAME',
PUBLISHER CHAR(20) field_format='PUBLISHER:NAME',
LOCATION CHAR(20) field_format='PUBLISHER:PLACE',
DATE INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=JSON file_name='biblio3.json';
```

and to populate it by:

```
INSERT INTO jsampall3 SELECT * FROM xsampall;
```

This is a simpler method. However, the issue is that this method cannot handle the multiple column values. This is why we inserted from `xsampall` not from `xsampall2`. How can we add the missing multiple authors in this table? Here again we must create a utility table able to handle JSON strings.
From Connect 1.07.0002

```
CREATE TABLE xj2 (ISBN CHAR(15), author VARCHAR(150) jpath='AUTHOR:*') ENGINE=CONNECT table_type=JSON
file_name='biblio3.json' option_list='jmode=1';
```

Before Connect 1.07.0002

```
CREATE TABLE xj2 (ISBN CHAR(15), author VARCHAR(150) field_format='AUTHOR:*')
  ENGINE=CONNECT table_type=JSON file_name='biblio3.json' option_list='jmode=1';
```

```
UPDATE xj2 SET author =
(SELECT json_array_grp(json_object(authorfn FIRSTNAME, authorln LASTNAME))
  FROM xsampall2 WHERE isbn = xj2.isbn);
```

Voilà !

Converting JSON Files

We have seen that json files can be formatted differently depending on the pretty option. In particular, big data files should be formatted with pretty equal to 0 when used by a CONNECT json table. The best and simplest way to convert a file from one format to another is to use the *Jfile_Make* function. Indeed this function makes a file of specified format using the syntax:

```
Jfile_Make(json_document, [file_name], [pretty]);
```

The file name is optional when the json document comes from a Jbin_File function because the returned structure makes it available. For instance, to convert back the json file tb.json to pretty= 0, this can be simply done by:

```
SELECT Jfile_Make(Jbin_File('tb.json'), 0);
```

Performance Consideration

MySQL and PostgreSQL have a JSON data type that is not just text but an internal encoding of JSON data. This is to save parsing time when executing JSON functions. Of course, the parse must be done anyway when creating the data and serializing must be done to output the result.

CONNECT directly works on character strings impersonating JSON values with the need of parsing them all the time but with the advantage of working easily on external data. Generally, this is not too penalizing because JSON data are often of some or reasonable size. The only case where it can be a serious problem is when working on a big JSON file.

Then, the file should be formatted or converted to *pretty=0*.

From Connect 1.7.002, this easily done using the Jfile_Convert function, for instance:

```
SELECT jfile_convert('bibdoc.json','bibdoc0.json',350);
```

Such a json file should not be used directly by JSON UDFs because they parse the whole file, even when only a subset is used. Instead, it should be used by a JSON table created on it. Indeed, JSON tables do not parse the whole document but just the item corresponding to the row they are working on. In addition, indexing can be used by the table as explained previously on this page.

Generally speaking, the maximum flexibility offered by CONNECT is by using JSON tables and JSON UDFs together. Some things are better handled by tables, other by UDFs. The tools are there but it is up to you to discover the best way to resolve your problems.

Bjson Files

Starting with Connect 1.7.002, *pretty=0* json files can be converted to a binary format that is a pre-parsed representation of json. This can be done with the Jfile_Bjson UDF function, for instance:

```
SELECT jfile_bjson('bigfile.json','binfile.json',3500);
```

Here the third argument, the record length, must 6 to 10 times larger than the lrecl of the initial json file because the parsed representation is bigger than the original json text representation.

Tables using such Bjson files must specify ‘Pretty=-1’ in the option list.

It is probably similar to the BSON used by MongoDB and PostgreSQL and permits to process queries up to 10 times faster than working on text json files. Indexing is also available for tables using this format making even more performance improvement. For instance, some queries on a json table of half a million rows, that were previously done in more than 10 seconds, took only 0.1 second when converted and indexed.

Here again, this has been remade to use the new way Json is handled. The files made using the bfile_bjson function are only from two to four times the size of the source files. This new representation is not compatible with the old one. Therefore, these files must be used with BSON tables only.

Specifying a JSON Table Encoding

An important feature of JSON is that strings should in UNICODE. As a matter of fact, all examples we have found on the Internet seemed to be just ASCII. This is because UNICODE is generally encoded in JSON files using UTF8 or UTF16 or UTF32.

To specify the required encoding, just use the data_charset CONNECT option or the native DEFAULT CHARSET option.

Retrieving JSON Data From MongoDB

Classified as a NoSQL database program, MongoDB uses JSON-like documents (BSON) grouped in collections. The simplest way, and only method available before Connect 1.6, to access MongoDB data was to export a collection to a JSON file. This produces a file having the pretty=0 format. Viewed as SQL, a collection is a table and documents are table rows.

Since CONNECT version 1.6, it is now possible to directly access MongoDB collections via their MongoDB C Driver. This is the purpose of the MONGO table type described later. However, JSON tables can also do it in a somewhat different way (providing MONGO support is installed as described for MONGO tables).

It is achieved by specifying the MongoDB connection URI while creating the table. For instance:

From Connect 1.7.002

```
CREATE OR REPLACE TABLE jinvent (
_id CHAR(24) NOT NULL,
item CHAR(12) NOT NULL,
instock VARCHAR(300) NOT NULL jpath='instock.*')
ENGINE=CONNECT table_type=JSON tabname='inventory' lrecl=512
CONNECTION='mongodb://localhost:27017';
```

Before Connect 1.7.002

```
CREATE OR REPLACE TABLE jinvent (
_id CHAR(24) NOT NULL,
item CHAR(12) NOT NULL,
instock VARCHAR(300) NOT NULL field_format='instock.*')
ENGINE=CONNECT table_type=JSON tabname='inventory' lrecl=512
CONNECTION='mongodb://localhost:27017';
```

In this statement, the *file_name* option was replaced by the *connection* option. It is the URI enabling to retrieve data from a local or remote MongoDB server. The *tabname* option is the name of the MongoDB collection that are used and the *dbname* option could have been used to indicate the database containing the collection (it defaults to the current database).

The way it works is that the documents retrieved from MongoDB are serialized and CONNECT uses them as if they were read from a file. This implies serializing by MongoDB and parsing by CONNECT and is not the best performance wise. CONNECT tries its best to reduce the data transfer when a query contains a reduced column list and/or a where clause. This way makes all the possibilities of the JSON table type available, such as calculated arrays.

However, to work on large JSON collations, using the MONGO table type is generally the normal way.

Note: JSON tables using the MongoDB access accept the specific MONGO options colist, filter and pipeline. They are described in the MONGO table chapter.

Summary of Options and Variables Used With JSON Tables

Options and variables that can be used when creating Json tables are listed here:

Table Option	Type	Description
ENGINE	String	Must be specified as CONNECT.
TABLE_TYPE	String	Must be JSON or BSON.
FILE_NAME	String	The optional file (path) name of the Json file. Can be absolute or relative to the current data directory. If not specified, it defaults to the table name and json file type.
DATA_CHARSET	String	Set it to 'utf8' for most Unicode Json documents.
LRECL	Number	The file record size for pretty < 2 json files.
HTTP	String	The HTTP of the server of REST queries.
URI	String	THE URI of REST queries

Table Option	Type	Description
CONNECTION*	String	Specifies a connection to MONGODB.
ZIPPED	Boolean	True if the json file(s) is/are zipped in one or several zip files.
MULTIPLE	Number	Used to specify a multiple file table.
SEP_CHAR	String	Set it to ':' for old tables using the old json path syntax.
CATFUNC	String	The catalog function (column) used when creating a catalog table.
OPTION_LIST	String	Used to specify all other options listed below.

(*) For Json tables connected to MongoDB, Mongo specific options can also be used.

Other options must be specified in the option list:

Table Option	Type	Description
DEPTHLEVEL	Number	Specifies the depth in the document CONNECT looks when defining columns by discovery or in catalog tables
PRETTY	Number	Specifies the format of the Json file (-1 for Bjson files)
EXPAND	String	The name of the column to expand.
OBJECT	String	The json path of the sub-document used for the table.
BASE	Number	The numbering base for arrays: 0 (the default) or 1.
LIMIT	Number	The maximum number of array values to use when concatenating, calculating or expanding arrays. Defaults to 50 (>= Connect 1.7.0003), 10 (<= Connect 1.7.0002).
FULLARRAY	Boolean	Used when creating with Discovery. Make a column for each value of arrays (up to LIMIT).
JMODE	Number	The Json mode (array of objects, array of arrays, or array of values) Only used when inserting new rows.
ACCEPT	Boolean	Keep null columns (for discovery).
AVGLEN	Number	An estimate average length of rows. This is used only when indexing and can be set if indexing fails by miscalculating the table max size.
STRINGIFY	String	Ask discovery to make a column to return the Json representation of this object.

Column options:

Column Option	Type	Description
JPATHFIELD_FORMAT	String	Defaults to the column name.
DATE_FORMAT	String	Specifies the date format into the Json file when defining a DATE, DATETIME or TIME column.

Variables used with Json tables are:

- connect_default_depth
- connect_json_null
- connect_json_all_path

- connect_force_bson

Notes

1. ↑ The value n can be 0 based or 1 based depending on the base table option. The default is 0 to match what is the current usage in the Json world but it can be set to 1 for tables created in old versions.
2. ↑ See for instance: json-functions, lib_mysqludf_json#readme and json_udf_functions_version_04
3. ↑ This will not work when CONNECT is compiled embedded

CONNECT MONGO Table Type: Accessing Collections from MongoDB

Classified as a NoSQL database program, MongoDB uses JSON-like documents (BSON) grouped in collections. The MONGO type is used to directly access MongoDB collections as tables.

Accessing MongDB from CONNECT

Accessing MongoDB from CONNECT can be done in different ways:

1. As a MONGO table via the MongoDB C Driver.
2. As a MONGO table via the MongoDB Java Driver.
3. As a JDBC table using some commercially available MongoDB JDBC drivers.
4. As a JSON table via the MongoDB C or Java Driver.

Using the MongoDB C Driver

This is currently not available from binary distributions but only for versions compiled from source. The preferred version of the MongoDB C Driver is 1.7, because they provide package recognition. What must be done is:

1. Install libbson and the MongoDB C Driver 1.7.
2. Configure, compile and install MariaDB.

With earlier versions of the Mongo C Driver, the additional include directories and libraries will have to be specified manually when compiling.

When possible, this is the preferred means of access because it does not require all the Java path settings etc. and is faster than using the Java driver.

Using the Mongo Java Driver

This is possible with all distributions including JDBC support, or compiling from source. With a binary distribution that does not enable the MONGO table type, it is possible to access MongoDB using an OEM module. See CONNECT OEM Table Example for details. The only additional things to do are:

1. Install the MongoDB Java Driver by downloading its jar file. Several versions are available. If possible use the latest version 3 one.
2. Add the path to it in the CLASSPATH environment variable or in the connect_class_path variable. This is like what is done to declare JDBC drivers.

Connection is established by new Java wrappers Mongo3Interface and Mongo2Interface. They are available in a JDBC distribution in the Mongo2.jar and Mongo3.jar files (previously JavaWrappers.jar). If version 2 of the Java Driver is used, specify “Version=2” in the option list when creating tables.

Using JDBC

See the documentation of the existing commercial JDBC Mongo drivers.

Using JSON

See the specific chapter of the JSON Table Type.

The following describes the MONGO table type.

CONNECT MONGO Tables

Creating and running MONGO tables requires a connection to a running local or remote MongoDB server.

A MONGO table is defined to access a MongoDB collection. The table rows are the collection documents. For instance, to create a table based on the MongoDB sample collection restaurants, you can do something such as the following:

```
CREATE TABLE resto (
_id VARCHAR(24) NOT NULL,
name VARCHAR(64) NOT NULL,
cuisine CHAR(200) NOT NULL,
borough CHAR(16) NOT NULL,
restaurant_id VARCHAR(12) NOT NULL)
ENGINE=CONNECT table_type=MONGO tabname='restaurants'
data_charset=utf8 CONNECTION='mongodb://localhost:27017';
```

Note: The used driver is by default the C driver if only the MongoDB C Driver is installed and the Java driver if only the MongoDB Java Driver is installed. If both are available, it can be specified by the DRIVER option to be specified in the option list and defaults to C.

Here we did not define all the items of the collection documents but only those that are JSON values. The database is test by default. The connection value is the URI used to establish a connection to a local or remote MongoDB server. The value shown in this example corresponds to a local server started with its default port. It is the default connection value for MONGO tables so we could have omit specifying it.

Using discovery is available. This table could have been created by:

```
CREATE TABLE resto
ENGINE=CONNECT table_type=MONGO tabname='restaurants'
data_charset=utf8 option_list='level=-1';
```

Here “depth=-1” is used to create only columns that are simple values (no array or object). Without this, with the default value “depth=0” the table had been created as:

```
CREATE TABLE `resto` (
  `_id` CHAR(24) NOT NULL,
  `address` VARCHAR(136) NOT NULL,
  `borough` CHAR(13) NOT NULL,
  `cuisine` CHAR(64) NOT NULL,
  `grades` VARCHAR(638) NOT NULL,
  `name` CHAR(98) NOT NULL,
  `restaurant_id` CHAR(8) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='MONGO' `TABNAME`='restaurants'
`DATA_CHARSET`='utf8';
```

Fixing Problems With mariadb-dump

In some case or some platforms, when CONNECT is set up for use with JDBC table types, this causes mariadb-dump with the –all-databases option to fail.

This was reported by Robert Dyas who found the cause of it and how to fix it (see MDEV-11238).

This occurs when the Java JRE “Usage Tracker” is enabled. In that case, Java creates a directory #mysql50#.oracle_jre_usage in the mysql data directory that shows up as a database but cannot be accessed via MySQL Workbench nor apparently backed up by mariadb-dump –all-databases.

Per the Oracle documentation () the
“Usage Tracker” is disabled by default. It is enabled only when creating the properties file /lib/management/usagetracker.properties. This turns out to be WRONG on some platforms as the file does exist by default on a new installation, and the existence of this file enables the usage tracker.

The solution on CentOS 7 with the Oracle JVM is to rename or delete the usagetracker.properties file (to disable it) and then delete the bogus folder it created in the mysql database directory, then restart.

For example, the following works:

```
sudo mv /usr/java/default/jre/lib/management/management.properties
/usr/java/default/jre/lib/management/management.properties.TRACKER-OFF
sudo reboot
sudo rm -rf  /var/lib/mysql/.oracle_jre_usage
sudo reboot
```

In this collection, the address column is a JSON object and the column grades is a JSON array. Unlike the JSON table, just specifying the column name with no Jpath result in displaying the JSON representation of them. For instance:

```
SELECT name, address FROM resto LIMIT 3;
```

name	address
Morris Park Bake Shop	{“building”:“1007”,“coord”:[-73.8561,40.8484], “street”:“Morris ParkAve”, “zipcode”:“10462”}
Wendy’S	{“building”:“469”,“coord”:[-73.9617,40.6629], “street”:“Flatbush Avenue”, “zipcode”:“11225”}
Reynolds Restaurant	{“building”:“351”,“coord”:[-73.9851,40.7677], “street”:“West 57Street”, “zipcode”:“10019”}

MongoDB Dot Notation

To address the items inside object or arrays, specify the Jpath in MongoDB syntax (if using Discovery, specify the Depth option accordingly):

From Connect 1.7.0002

```
CREATE TABLE newresto (
_id VARCHAR(24) NOT NULL,
name VARCHAR(64) NOT NULL,
cuisine CHAR(200) NOT NULL,
borough CHAR(16) NOT NULL,
street VARCHAR(65) jpath='address.street',
building CHAR(16) jpath='address.building',
zipcode CHAR(5) jpath='address.zipcode',
grade CHAR(1) jpath='grades.0.grade',
score INT(4) NOT NULL jpath='grades.0.score',
`date` DATE jpath='grades.0.date',
restaurant_id VARCHAR(255) NOT NULL)
ENGINE=CONNECT table_type=MONGO tabname='restaurants'
data_charset=utf8 CONNECTION='mongodb://localhost:27017';
```

Before Connect 1.7.0002

```
CREATE TABLE newresto (
_id VARCHAR(24) NOT NULL,
name VARCHAR(64) NOT NULL,
cuisine CHAR(200) NOT NULL,
borough CHAR(16) NOT NULL,
street VARCHAR(65) field_format='address.street',
building CHAR(16) field_format='address.building',
zipcode CHAR(5) field_format='address.zipcode',
grade CHAR(1) field_format='grades.0.grade',
score INT(4) NOT NULL field_format='grades.0.score',
`date` DATE field_format='grades.0.date',
restaurant_id VARCHAR(255) NOT NULL)
ENGINE=CONNECT table_type=MONGO tabname='restaurants'
data_charset=utf8 CONNECTION='mongodb://localhost:27017';
```

If this is not done, the Oracle JVM will start the usage tracker, which will create the hidden folder .oracle_jre_usage in the mysql home directory, which will cause a mariadb-dump of the server to fail.

```
SELECT name, street, score, DATE FROM newresto LIMIT 5;
```

name	street	score	date
Morris Park Bake Shop	Morris Park Ave	2	03/03/2014
Wendy'S	Flatbush Avenue	8	30/12/2014
Dj Reynolds Pub And Restaurant	West 57 Street	2	06/09/2014
Riviera Caterer	Stillwell Avenue	5	10/06/2014
Tov Kosher Kitchen	63 Road	20	24/11/2014

MONGO Specific Options

The MongoDB syntax for Jpath does not allow the CONNECT specific items on arrays. The same effect can still be obtained by a different way. For this, additional options are used when creating MONGO tables.

Option	Type	Description
Colist	String	Options to pass to the MongoDB cursor.
Filter	String	Query used by the MongoDB cursor.
Pipeline*	Boolean	If True, Colist is a pipeline.
Fullarray*	Boolean	Used when creating with Discovery.
Driver*	String	C or Java.
Version*	Integer	The Java Driver version (defaults to 3)

- : To be specified in the option list.

Note: For the content of these options, refer to the MongoDB documentation.

Colist Option

Used to pass different options when making the MongoDB cursor used to retrieve the collation documents. One of them is the projection, allowing to limit the items retrieved in documents. It is hardly useful because this limitation is made automatically by CONNECT. However, it can be used when using discovery to eliminate the _id (or another) column when you are not willing to keep it:

```
CREATE TABLE restest
ENGINE=CONNECT table_type=MONGO tabname='restaurants'
data_charset=utf8 option_list='depth=-1'
colist='{"projection":{"_id":0},"limit":5}';
```

In this example, we added another cursor option, the limit option that works like the limit SQL clause.

This additional option works only with the C driver. When using the Java driver, colist should be:

```
colist='{"_id":0}';
```

And limit would be specified with select statements.

Note: When used with a JSON table, to specify the projection list (or 'all' to get all columns) makes JPATH to be Connect Json paths, not MongoDB ones, allowing JPATH options not available to MongoDB.

Filter Option

This option is used to specify a "filter" that works as a where clause on the table. Supposing we want to create a table restricted to the restaurant making English cuisine that are not located in the Manhattan borough, we can do it by:

```
CREATE TABLE english
ENGINE=CONNECT table_type=MONGO tabname='restaurants'
data_charset=utf8
colist='{"projection":{"cuisine":0}}'
filter='{"cuisine":"English","borough":{"$ne":"Manhattan"}}'
option_list='Depth=-1';
```

And if we ask:

```
SELECT * FROM english;
```

This query will return:

_id	borough	name	restaurant_id
58ada47de5a51ddfcd5ee1f3	Brooklyn	The Park Slope Chipshop	40816202
58ada47de5a51ddfcd5ee999	Brooklyn	Chip Shop	41076583
58ada47ee5a51ddfcd5f13d5	Brooklyn	The Monro	41660253
58ada47ee5a51ddfcd5f176e	Brooklyn	Dear Bushwick	41690534
58ada47ee5a51ddfcd5f1e91	Queens	Snowdonia Pub	50000290

Pipeline Option

When this option is specified as true (by YES or 1) the Colist option contains a MongoDB pipeline applying to the table collation. This is a powerful mean for doing things such as expanding arrays like we do with JSON tables. For instance:

```
CREATE TABLE resto2 (
name VARCHAR(64) NOT NULL,
borough CHAR(16) NOT NULL,
DATE DATETIME NOT NULL,
grade CHAR(1) NOT NULL,
score INT(4) NOT NULL)
ENGINE=CONNECT table_type=MONGO tabname='restaurants' data_charset=utf8
colist='{"pipeline":[{"$match":{"cuisine":"French"}},{"$unwind":"$grades"},{"$project":
{"_id":0,"name":1,"borough":1,"date":"$grades.date","grade":"$grades.grade","score":"$grades.score"}}]}'
option_list='Pipeline=1';
```

In this pipeline "$match" is an early filter, "$unwind" means that the grades array are expanded (one Document for each array values) and "$project" eliminates the _id and cuisine columns and gives the Jpath for the date, grade and score columns.

```
SELECT name, grade, score, DATE FROM resto2
WHERE borough = 'Bronx';
```

This query replies:

name	grade	score	date
Bistro Sk	A	10	21/11/2014 01:00:00
Bistro Sk	A	12	19/02/2014 01:00:00
Bistro Sk	B	18	12/06/2013 02:00:00

This make possible to get things like we do with JSON tables:

```
SELECT name, AVG(score) average FROM resto2
GROUP BY name HAVING average >= 25;
```

Can be used to get the average score inside the grades array.

name	average
Bouley Botanical	25,0000
Cheri	46,0000
Graine De Paris	30,0000
Le Pescadeux	29,7500

Fullarray Option

This option, like the Depth option, is only interpreted when creating a table with Discovery (meaning not specifying the columns). It tells CONNECT to generate a column for all existing values in the array. For instance, let us see the MongoDB collection tar by:

From Connect 1.7.0002

```
CREATE TABLE seetar (
Collection VARCHAR(300) NOT NULL jpath='*')
ENGINE=CONNECT table_type=MONGO tabname=tar;
```

Before Connect 1.7.0002

```
CREATE TABLE seetar (
Collection VARCHAR(300) NOT NULL field_format='*')
ENGINE=CONNECT table_type=MONGO tabname=tar;
```

The format '*' indicates we want to see the Json documents. This small collection is:

Collection
{"_id":{"$oid":"58f63a5099b37d9c930f9f3b"},"item":"journal","prices":[87.0,45.0,63.0,12.0,78.0]}
{"_id":{"$oid":"58f63a5099b37d9c930f9f3c"},"item":"notebook","prices":[123.0,456.0,789.0]}

The Fullarray option can be used here to generate enough columns to see all the prices of the document prices array.

```
CREATE TABLE tar
ENGINE=CONNECT table_type=MONGO
colist='{"projection":{"_id":0}}'
option_list='depth=1,Fullarray=YES';
```

The table has been created as:

From Connect 1.7.0002

```
CREATE TABLE `tar` (
  `item` CHAR(8) NOT NULL,
  `prices_0` DOUBLE(12,6) NOT NULL `JPATH`='prices.0',
  `prices_1` DOUBLE(12,6) NOT NULL `JPATH`='prices.1',
  `prices_2` DOUBLE(12,6) NOT NULL `JPATH`='prices.2',
  `prices_3` DOUBLE(12,6) DEFAULT NULL `JPATH`='prices.3',
  `prices_4` DOUBLE(12,6) DEFAULT NULL `JPATH`='prices.4'
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='MONGO' `COLIST`='{"projection":{"_id":0}}'
`OPTION_LIST`='depth=1,Fullarray=YES';
```

Before Connect 1.7.0002

```
CREATE TABLE `tar` (
  `item` CHAR(8) NOT NULL,
  `prices_0` DOUBLE(12,6) NOT NULL `FIELD_FORMAT`='prices.0',
  `prices_1` DOUBLE(12,6) NOT NULL `FIELD_FORMAT`='prices.1',
  `prices_2` DOUBLE(12,6) NOT NULL `FIELD_FORMAT`='prices.2',
  `prices_3` DOUBLE(12,6) DEFAULT NULL `FIELD_FORMAT`='prices.3',
  `prices_4` DOUBLE(12,6) DEFAULT NULL `FIELD_FORMAT`='prices.4'
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='MONGO' `COLIST`='{"projection":{"_id":0}}'
`OPTION_LIST`='level=1,Fullarray=YES';
```

And is displayed as:

item	prices_0	prices_1	prices_2	prices_3	prices_4
journal	87.00	45.00	63.00	12.00	78.00
notebook	123.00	456.00	789.00	NULL	NULL

Create, Read, Update and Delete Operations

All modifying operations are supported. However, inserting into arrays must be done in a specific way. Like with the Fullarray option, we must have enough columns to specify the array values. For instance, we can create a new table by:

From Connect 1.7.0002

```
CREATE TABLE testing (
n INT NOT NULL,
m CHAR(12) NOT NULL,
surname CHAR(16) NOT NULL jpath='person.name.first',
name CHAR(16) NOT NULL jpath='person.name.last',
age INT(3) NOT NULL jpath='person.age',
price_1 DOUBLE(8,2) jpath='d.0',
price_2 DOUBLE(8,2) jpath='d.1',
price_3 DOUBLE(8,2) jpath='d.2')
ENGINE=CONNECT table_type=MONGO tabname='tin'
CONNECTION='mongodb://localhost:27017';
```

Before Connect 1.7.0002

```
CREATE TABLE testing (
n INT NOT NULL,
m CHAR(12) NOT NULL,
surname CHAR(16) NOT NULL field_format='person.name.first',
name CHAR(16) NOT NULL field_format='person.name.last',
age INT(3) NOT NULL field_format='person.age',
price_1 DOUBLE(8,2) field_format='d.0',
price_2 DOUBLE(8,2) field_format='d.1',
price_3 DOUBLE(8,2) field_format='d.2')
ENGINE=CONNECT table_type=MONGO tabname='tin'
CONNECTION='mongodb://localhost:27017';
```

Now it is possible to populate it by:

```
INSERT INTO testing VALUES
(1789, 'Welcome', 'Olivier','Bertrand',56, 3.14, 2.36, 8.45),
(1515, 'Hello', 'John','Smith',32, 65.17, 98.12, NULL),
(2014, 'Coucou', 'Foo','Bar',20, -1.0, 74, 81356);
```

The result are:

n	m	surname	name	age	price_1	price_2	price_3
1789	Welcome	Olivier	Bertrand	56	3,14	2,36	8,45
1515	Hello	John	Smith	32	65,17	98,12	NULL
2014	Coucou	Foo	Bar	20	-1	74	81356

Note: If the collection does not exist yet when creating the table and inserting in it, MongoDB creates it automatically.

It can be updated by queries such as:

```
UPDATE tintin SET price_3 = 83.36 WHERE n = 2014;
```

To look how the array is generated, let us create another table:

From Connect 1.7.0002

```
CREATE TABLE tintin (
n INT NOT NULL,
name CHAR(16) NOT NULL jpath='person.name.first',
prices VARCHAR(255) jpath='d')
ENGINE=CONNECT table_type=MONGO tabname='tin';
```

Before Connect 1.7.002

```
CREATE TABLE tintin (
n INT NOT NULL,
name CHAR(16) NOT NULL field_format='person.name.first',
prices VARCHAR(255) field_format='d')
ENGINE=CONNECT table_type=MONGO tabname='in';
```

This table is displayed as:

From Connect 1.7.0002

n	name	prices
1789	Olivier	[3.1400000000000001243,2.3599999999999998757,8.4499999999999992895]
1515	John	[65.170000000000001705,98.120000000000004547,null]
2014	Foo	[null,74.0,83.359999999999999432]

Before Connect 1.7.002

n	name	prices
1789	Olivier	[3.14, 2.36, 8.45]
1515	John	[65.17, 98.12]
2014	Foo	[, 74.0, 83.36]

Note: This last table can be used to make array calculations like with JSON tables using the JSON UDF functions. For instance:

```
SELECT name, jsonget_real(prices,'[+]') sum_prices, jsonget_real(prices,'[!]') avg_prices FROM tintin;
```

This query returns:

name	sum_prices	avg_prices
Olivier	13.95	4.65
John	163.29	81.64
Foo	157,36	78.68

Note: When calculating on arrays, null values are ignored.

Status of MONGO Table Type

This table type is still under development. It has significant advantages over the JSON type to access MongoDB collections. Firstly, the access being direct, tables are always up to date whether the collection has been modified by another application. Performance wise, it can be faster than JSON, because most processing is done by MongoDB on BSON, its internal representation of JSON data, which is designed to optimize all operations. Note that using the MongoDB C Driver can be faster than using the MongoDB Java Driver.

Current Restrictions

- Option “CATFUNC=tables” is not implemented yet.
- Options SRCDEF and EXECSRC do not apply to MONGO tables.

CONNECT MYSQL Table Type: Accessing MySQL/MariaDB Tables

This table type uses libmysql API to access a MySQL or MariaDB table or view. This table must be created on the current server or on another local or remote server. This is similar to what the FederatedX storage engine provides with some differences.

Currently the Federated-like syntax can be used to create such a table, for instance:

```
CREATE TABLE essai (
  num INTEGER(4) NOT NULL,
  line CHAR(15) NOT NULL)
ENGINE=CONNECT table_type=MYSQL
CONNECTION='mysql://root@localhost/test/people';
```

The connection string can have the same syntax as that used by FEDERATED

```
scheme://username:password@hostname:port/database/tablename
scheme://username@hostname/database/tablename
scheme://username:password@hostname/database/tablename
scheme://username:password@hostname/database/tablename
```

However, it can also be mixed with connect standard options. For instance:

```
CREATE TABLE essai (
  num INTEGER(4) NOT NULL,
  line CHAR(15) NOT NULL)
ENGINE=CONNECT table_type=MYSQL dbname=test tabname=people
CONNECTION='mysql://root@localhost';
```

It can also be specified as a reference to a federated server:

```
connection="connection_one"
connection="connection_one/table_foo"
```

The pure (deprecated) CONNECT syntax is also accepted:

```
CREATE TABLE essai (
  num INTEGER(4) NOT NULL,
  line CHAR(15) NOT NULL)
ENGINE=CONNECT table_type=MYSQL dbname=test tabname=people
option_list='user=root,host=localhost';
```

The specific connection items are:

Option	Default value	Description
Table	The table name	The name of the table to access.
Database	The current DB name	The database where the table is located.
Host	localhost*	The host of the server, a name or an IP address.
User	The current user	The connection user name.
Password	No password	An optional user password.
Port	The currently used port	The port of the server.
Quoted	0	1 if remote Tabname must be quoted.

- - When the host is specified as “localhost”, the connection is established on Linux using Linux sockets. On Windows, the connection is established by default using shared memory if it is enabled. If not, the TCP protocol is used. An alternative is to specify the host as “.” to use a named pipe connection (if it is enabled). This makes possible to use these table types with server skipping networking.

Caution: Take care not to refer to the MYSQL table itself to avoid an infinite loop!

MYSQL table can refer to the current server as well as to another server. Views can be referred by name or directly giving a source definition, for instance:

```
CREATE TABLE grp ENGINE=CONNECT table_type=mysql
CONNECTION='mysql://root@localhost/test/people'
SRCDEF='select title, count(*) as cnt from employees group by title';
```

When specified, the columns of the mysql table must exist in the accessed table with the same name, but can be only a subset of them and specified in a different order. Their type must be a type supported by CONNECT and, if it is not identical to the type of the accessed table matching column, a conversion can be done according to the rules given in Data type conversion.

Note: For columns prone to be targeted by a where clause, keep the column type compatible with the source table column type (numeric or character) to have a correct rephrasing of the where clause.

If you do not want to restrict or change the column definition, do not provide it and leave CONNECT get the column definition from the remote server. For instance:

```
CREATE TABLE essai ENGINE=CONNECT table_type=MYSQL
CONNECTION='mysql://root@localhost/test/people';
```

This will create the *essai* table with the same columns than the people table. If the target table contains CONNECT incompatible type columns, see Data type conversion to know how these columns can be converted or skipped.

Charset Specification

When accessing the remote table, CONNECT sets the connection charset set to the default local table charset as the FEDERATED engine does.

Do not specify a column character set if it is different from the table default character set even when it is the case on the remote table. This is because the remote column is translated to the local table character set when reading it. This is the default but it can be modified by the setting the character_set_results variable of the target server. If it must keep its setting, for instance to UTF8 when containing Unicode characters, specify the local default charset to its character set.

This means that it is not possible to correctly retrieve a remote table if it contains columns having different character sets. A solution is to retrieve it by several local tables, each accessing only columns with the same character set.

Indexing of MYSQL tables

Indexes are rarely useful with MYSQL tables. This is because CONNECT tries to access only the requested rows. For instance if you ask:

```
SELECT * FROM essai WHERE num = 23;
```

CONNECT will construct and send to the server the query:

```
SELECT num, line FROM people WHERE num = 23
```

If the *people* table is indexed on *num*, indexing are used on the remote server. This, in all cases, will limit the amount of data to retrieve on the network.

However, an index can be specified for columns that are prone to be used to join another table to the MYSQL table. For instance:

```
SELECT d.id, d.name, f.dept, f.salary
FROM loc_tab d STRAIGHT_JOIN cnc_tab f ON d.id = f.id
WHERE f.salary > 10000;
```

If the *id* column of the remote table addressed by the *cnc_tab* MYSQL table is indexed (which is likely if it is a key) you should also index the *id* column of the MYSQL *cnc_tab* table. If so, using “remote” indexing as does FEDERATED, only the useful rows of the remote table are retrieved during the join process. However, because these rows are retrieved by separate SELECT statements, this is useful only when retrieving a few rows of a big table.

In particular, you should not specify an index for columns not used for joining and above all DO NOT index a joined column if it is not indexed in the remote table. This would cause multiple scans of the remote table to retrieve the joined rows one by one.

Data Modifying Operations

The CONNECT MYSQL type supports SELECT and INSERT and a somewhat limited form of UPDATE and DELETE. These are described below.

The MYSQL type uses similar methods than the ODBC type to implement the INSERT,UPDATE and DELETE commands. Refer to the ODBC chapter for the restrictions concerning them.

For the UPDATE and DELETE commands, there are fewer restrictions because the remote server being a MySQL server, the syntax of the command are always acceptable by the remote server.

For instance, you can freely use keywords like IGNORE or LOW_PRIORITY as well as scalar functions in the SET and WHERE clauses.

However, there is still an issue on multi-table statements. Let us suppose you have a *t1* table on the remote server and want to execute a query such as:

```
UPDATE essai AS x SET line = (SELECT msg FROM t1 WHERE id = x.num)
WHERE num = 2;
```

When parsed locally, you will have errors if no *t1* table exists or if it does not have the referenced columns. When *t1* does not exist, you can overcome this issue by creating a local dummy *t1* table:

```
CREATE TABLE t1 (id INT, msg CHAR(1)) ENGINE=BLACKHOLE;
```

This will make the local parser happy and permit to execute the command on the remote server. Note however that having a local MySQL table defined on the remote *t1* table does not solve the problem unless it is also names *t1* locally.

This is why, to permit to have all types of commands executed by the data source without any restriction, CONNECT provides a specific MySQL table subtype described now.

Sending commands to a MariaDB Server

This can be done like for ODBC or JDBC tables by defining a specific table that are used to send commands and get the result of their execution..

```
  number int(5) not null flag=1,
CREATE TABLE send (
  command VARCHAR(128) NOT NULL,
  warnings INT(4) NOT NULL flag=3,
  message VARCHAR(255) flag=2)
ENGINE=CONNECT table_type=mysql
CONNECTION='mysql://user@host/database'
option_list='Execsrc=1,Maxerr=2';
```

The key points in this create statement are the EXECSRC option and the column definition.

The EXECSRC option tells that this table are used to send commands to the MariaDB server. Most of the sent commands do not return result set. Therefore, the table columns are used to specify the command to be executed and to get the result of the execution. The name of these columns can be chosen arbitrarily, their function coming from the FLAG value:

Flag=0:	The command to execute (the default)
Flag=1:	The number of affected rows, or the result number of columns if the command would return a result set.
Flag=2:	The returned (eventually error) message.
Flag=3:	The number of warnings.

How to use this table and specify the command to send? By executing a command such as:

```
SELECT * FROM send WHERE command = 'a command';
```

This will send the command specified in the WHERE clause to the data source and return the result of its execution. The syntax of the WHERE clause must be exactly as shown above. For instance:

```
SELECT * FROM send WHERE command =
'CREATE TABLE people (
num integer(4) primary key autoincrement,
line char(15) not null';
```

This command returns:

command	warnings	number	message
CREATE TABLE people (num integer(4) primary key aut…	0	0	Affected rows

Sending several commands in one call

It can be faster to execute because there are only one connection for all of them. To send several commands in one call, use the following syntax:

```
SELECT * FROM send WHERE command IN (
"update people set line = 'Two' where id = 2",
"update people set line = 'Three' where id = 3");
```

When several commands are sent, the execution stops at the end of them or after a command that is in error. To continue after n errors, set the option maxerr=*n* (0 by default) in the option list.

Note 1: It is possible to specify the SRCDEF option when creating an EXECSRC table. It are the command sent by default when a WHERE clause is not specified.

Note 2: Backslashes inside commands must be escaped. Simple quotes must be escaped if the command is specified between simple quotes, and double quotes if it is specified between double quotes.

Note 3: Sent commands apply in the specified database. However, they can address any table within this database.

Note 4: Currently, all commands are executed in mode AUTOCOMMIT.

Retrieving Warnings and Notes

If a sent command causes warnings to be issued, it is useless to resend a “show warnings” command because the MariaDB server is opened and closed when sending commands. Therefore, getting warnings requires a specific (and tricky) way.

To indicate that warning text must be added to the returned result, you must send a multi-command query containing “pseudo” commands that are not sent to the server but directly interpreted by the EXECSRC table. These “pseudo” commands are:

Warning	To get warnings
Note	To get notes
Error	To get errors returned as warnings (?)

Note that they must be spelled (case insensitive) exactly as above, no final “s”. For instance:

```
SELECT * FROM send WHERE command IN ('Warning','Note',
'drop table if exists try',
'create table try (id int key auto_increment, msg varchar(32) not
null) engine=aria',
"insert into try(msg) values('One'),(NULL),('Three') ",
"insert into try values(2,'Deux') on duplicate key update msg =
'Two'",
"insert into try(message) values('Four'),('Five'),('Six')",
'insert into try(id) values(NULL)',
"update try set msg = 'Four' where id = 4",
'select * from try');
```

This can return something like this:

command	warnings	number	message
drop table if exists try	1	0	Affected rows
Note	0	1051	Unknown table ‘try’
create table try (id int key auto_increment, msg…	0	0	Affected rows
insert into try(msg) values(‘One’),(NULL),(‘Three’)	1	3	Affected rows
Warning	0	1048	Column ‘msg’ cannot be null
insert into try values(2,‘Deux’) on duplicate key…	0	2	Affected rows
insert into try(msge) values(‘Four’),(‘Five’),(‘Six’)	0	1054	Unknown column ‘msge’ in ‘field list’
insert into try(id) values(NULL)	1	1	Affected rows
Warning	0	1364	Field ‘msg’ doesn’t have a default value
update try set msg = ‘Four’ where id = 4	0	1	Affected rows
select * from try	0	2	Result set columns

The execution continued after the command in error because of the MAXERR option. Normally this would have stopped the execution.

Of course, the last “select” command is useless here because it cannot return the table contain. Another MYSQL table without the EXECSRC option and with proper column definition should be used instead.

Connection Engine Limitations

Data types

There is a maximum key.index length of 255 bytes. You may be able to declare the table without an index and rely on the engine condition pushdown and remote schema.

The following types can’t be used:

- BIT
- BINARY
- TINYBLOB, BLOB, MEDIUMBLOB, LONGBLOB
- TINYTEXT, MEDIUMTEXT, LONGTEXT
- ENUM
- SET
- Geometry types

Note: TEXT is allowed. However, the handling depends on the values given to the connect_type_conv and connect_conv_size system variables, and by default no conversion of TEXT columns is permitted.

SQL Limitations

The following SQL queries are not supported

- REPLACE INTO
- INSERT ... ON DUPLICATE KEY UPDATE

CONNECT MYSQL versus FEDERATED

The CONNECT MYSQL table type should not be regarded as a replacement for the FEDERATED(X) engine. The main use of the MYSQL type is to access other engine tables as if they were CONNECT tables. This was necessary when accessing tables from some CONNECT table types such as TBL, XCOL, OCCUR, or PIVOT that are designed to access CONNECT tables only. When their target table is not a
CONNECT table, these types are silently using internally an intermediate MYSQL table.

However, there are cases where you can use MYSQL CONNECT tables yourself, for instance:

1. When the table are used by a TBL table. This enables you to specify the connection parameters for each sub-table and is more efficient than using a local FEDERATED sub-table.
2. When the desired returned data is directly specified by the SRCDEF option.
   This is great to let the remote server do most of the job, such as grouping and/or joining tables. This cannot be done with the FEDERATED engine.
3. To take advantage of the push_cond facility that adds a where clause to the command sent to the remote table. This restricts the size of the result set and can be crucial for big tables.
4. For tables with the EXECSRC option on.
5. When doing tests. For instance to check a connection string.

If you need multi-table updating, deleting, or bulk inserting on a remote table, you can alternatively use the FEDERATED engine or a “send” table specifying the EXECSRC option on.

CONNECT - NoSQL Table Types

They are based on files that do not match the relational format but often represent hierarchical data. CONNECT can handle JSON, INI-CFG, XML, and some HTML files.

The way it is done is different from what MySQL or PostgreSQL does. In addition to including in a table some column values of a specific data format (JSON, XML) to be handled by specific functions, CONNECT can directly use JSON, XML or INI files that are produced by other applications, and this is the table definition that describes where and how the contained information must be retrieved.

This is also different from what MariaDB does with dynamic columns, which is close to what MySQL and PostgreSQL do with the JSON column type.

Note: The LEVEL option used with these tables should, from Connect 1.07.0002, be specified as DEPTH. Also, what was specified with the FIELD_FORMAT column option should now also be specified using JPATH or XPATH.

CONNECT OCCUR Table Type

Similarly to the XCOL table type, `OCCUR` is an extension to the PROXY type when referring to a table or view having several columns containing the same kind of data. It enables having a different view of the table where the data from

these columns are put in a single column, eventually causing several rows to be generated from one row of the object table. For example, supposing we have a_pets_ table:

name	dog	cat	rabbit	bird	fish
John	2	0	0	0	0
Bill	0	1	0	0	0
Mary	1	1	0	0	0
Lisbeth	0	0	2	0	0
Kevin	0	2	0	6	0
Donald	1	0	0	0	3

We can create an occur table by:

```
CREATE TABLE xpet (
  name VARCHAR(12) NOT NULL,
  race CHAR(6) NOT NULL,
  NUMBER INT NOT NULL)
ENGINE=CONNECT table_type=occur tabname=pets
option_list='OccurCol=number,RankCol=race'
Colist='dog,cat,rabbit,bird,fish';
```

When displaying it by

```
SELECT * FROM xpet;
```

We will get the result:

name	race	number
John	dog	2
Bill	cat	1
Mary	dog	1
Mary	cat	1
Lisbeth	rabbit	2
Kevin	cat	2
Kevin	bird	6
Donald	dog	1
Donald	fish	3

First of all, the values of the column listed in the Colist option have been put in a unique column whose name is given by the OccurCol option. When several columns have non null (or pseudo-null) values, several rows are generated, with the other normal columns values repeated.

In addition, an optional special column was added whose name is given by the RankCol option. This column contains the name of the source column from which the value of the OccurCol column comes from. It permits here to know the race of the pets whose number is given in *number*.

This table type permit to make queries that would be more complicated to make on the original tables. For instance to know who as more than 1 pet of a kind, you can simply ask:

```
SELECT * FROM xpet WHERE NUMBER > 1;
```

You will get the result:

name	race	number
John	dog	2
Lisbeth	rabbit	2
Kevin	cat	2
Kevin	bird	6
Donald	fish	3

Note 1: Like for XCOL tables, no row multiplication for queries not implying the Occur column.

Note 2: Because the OccurCol was declared “not null” no rows were generated for null or pseudo-null values of the column list. If the OccurCol is declared as nullable, rows are also generated for columns containing null or pseudo-null values.

Occur tables can be also defined from views or source definition. Also, CONNECT is able to generate the column definitions if not specified:

```
CREATE TABLE ocsrc ENGINE=CONNECT table_type=occur
colist='january,february,march,april,may,june,july,august,september,
october,november,december' option_list='rankcol=month,occurcol=day'
srcdef='select ''Foo'' name, 8 january, 7 february, 2 march, 1 april,
  8 may, 14 june, 25 july, 10 august, 13 september, 22 october, 28
  november, 14 december';
```

This table is displayed as:

name	month	day
Foo	january	8
Foo	february	7
Foo	march	2
Foo	april	1
Foo	may	8
Foo	june	14
Foo	july	25
Foo	august	10
Foo	september	13
Foo	october	22
Foo	november	28
Foo	december	14

CONNECT ODBC Table Type: Accessing Tables From Another DBMS

ODBC (Open Database Connectivity) is a standard API for accessing database management systems (DBMS). CONNECT uses this API to access data contained in other DBMS without having to implement a specific application for each one. An exception is the access to MySQL that should be done using the MYSQL table type.

Note: On Linux, unixODBC must be installed.

These tables are given the type ODBC. For example, if a “Customers” table is contained in an Access™ database you can define it with a command such as:

```
CREATE TABLE Customer (
  CustomerID VARCHAR(5),
  CompanyName VARCHAR(40),
  ContactName VARCHAR(30),
  ContactTitle VARCHAR(30),
  Address VARCHAR(60),
  City VARCHAR(15),
  Region VARCHAR(15),
  PostalCode VARCHAR(10),
  Country VARCHAR(15),
  Phone VARCHAR(24),
  Fax VARCHAR(24))
ENGINE=CONNECT table_type=ODBC block_size=10
tabname='Customers'
CONNECTION='DSN=MS Access Database;DBQ=C:/Program
Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

Tabname option defaults to the table name. It is required if the source table name is different from the name of the CONNECT table. Note also that for some data sources this name is case sensitive.

Often, because CONNECT can retrieve the table description using ODBC catalog functions, the column definitions can be unspecified. For instance this table can be simply created as:

```
CREATE TABLE Customer ENGINE=CONNECT table_type=ODBC
  block_size=10 tabname='Customers'
  CONNECTION='DSN=MS Access Database;DBQ=C:/Program Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

The `BLOCK_SIZE` specification are used later to set the RowsetSize when retrieving rows from the ODBC table. A reasonably large RowsetSize can greatly accelerate the fetching process.

If you specify the column description, the column names of your table must exist in the data source table. However, you are not obliged to define all the data source columns and you can change the order of the columns. Some type conversion can also be done if appropriate. For instance, to access the FireBird sample table EMPLOYEE, you could define your table as:

```
CREATE TABLE empodbc (
  EMP_NO SMALLINT(5) NOT NULL,
  FULL_NAME VARCHAR(37) NOT NULL),
  PHONE_EXT VARCHAR(4) NOT NULL,
  HIRE_DATE DATE,
  DEPT_NO SMALLINT(3) NOT NULL,
  JOB_COUNTRY VARCHAR(15),
  SALARY DOUBLE(12,2) NOT NULL)
ENGINE=CONNECT table_type=ODBC tabname='EMPLOYEE'
CONNECTION='DSN=firebird';
```

This definition ignores the FIRST_NAME, LAST_NAME, JOB_CODE, and JOB_GRADE columns. It places the FULL_NAME last column of the original table in second position. The type of the HIRE_DATE column was changed from *timestamp* to *date* and the type of the DEPT_NO column was changed from *char* to *integer*.

Currently, some restrictions apply to ODBC tables:

1. Cursor type is forward only (sequential reading).
2. No indexing of ODBC tables (do not specify any columns as key). However, because CONNECT can often add a where clause to the query sent to the data source, indexing are used by the data source if it supports it. (Remote indexing is available with version 1.04, released with MariaDB 10.1.6)
3. CONNECT ODBC supports SELECT and INSERT. UPDATE and DELETE are also supported in a somewhat restricted way (see below). For other operations, use an ODBC table with the EXECSRC option (see below) to directly send proper commands to the data source.

Random Access of ODBC Tables

In CONNECT version 1.03 (until MariaDB 10.1.5) ODBC tables are not indexable. Version 1.04 (from MariaDB 10.1.6) adds remote indexing facility to the ODBC table type.

However, some queries require random access to an ODBC table; for instance when it is joined to another table or used in an order by queries applied to a long column or large tables.

There are several ways to enable random (position) access to a CONNECT ODBC table. They are dependent on the following table options:

Option	Type	Used For
Block_Size	Integer	Specifying the rowset size.
Memory*	Integer	Storing the result set in memory.
Scrollable*	Boolean	Using a scrollable cursor.

`*` - To be specified in the option_list.

When dealing with small tables, the simpler way to enable random access is to specify a rowset size equal or larger than the table size (or the result set size if a push down where clause is used). This means that the whole result is in memory on the first fetch and CONNECT will use it for further positional accesses.

Another way to have the result set in memory is to use the memory option. This option can be set to the following values:

0. No memory used (the default). Best when the table is read sequentially as in SELECT statements with only eventual WHERE clauses.**1.** Memory size required is calculated during the first sequential table read. The allocated memory is filled during the second sequential read. Then the table rows are retrieved from the memory. This should be used when the table are accessed several times randomly, such as in sub-selects or being the target table of a join.**2.** A first query is executed to get the result set size and the needed memory is allocated. It is filled on the first sequential reading. Then random access of the table is possible. This can be used in the case of ORDER BY clauses, when MariaDB uses position reading.

Note that the best way to handle ORDER BY is to set the max_length_for_sort_data variable to a larger value (its default value is 1024 that is pretty small). Indeed, it requires less memory to be used, particularly when a WHERE clause limits the retrieved data set. This is because in the case of an order by query, MariaDB firstly retrieves the sequentially the result set and the position of each records. Often the sort can be done from the result set if it is not too big. But if too big, or if it implies some “long” columns, only the positions are sorted and MariaDB retrieves the final result from the table read in random order. If setting the max_length_for_sort_data variable is not feasible or does not work, to be able to retrieve table data from memory after the first sequential read, the memory option must be set to 2.

For tables too large to be stored in memory another possibility is to make your table to use a scrollable cursor. In this case each randomly accessed row can be retrieved from the data source specifying its cursor position, which is reasonably fast. However, scrollable cursors are not supported by all data sources.

With CONNECT version 1.04 (from MariaDB 10.1.6), another way to provide random access is to specify some columns to be indexed. This should be done only when the corresponding column of the source table is also indexed. This should be used for tables too large to be stored in memory and is similar to the remote indexing used by the MYSQL table type and by the FEDERATED engine.

There remains the possibility to extract data from the external table and to construct another table of any file format from the data source. For instance to construct a fixed formatted DOS table containing the CUSTOMER table data, create the table as

```
CREATE TABLE Custfix ENGINE=CONNECT File_name='customer.txt'
  table_type=fix block_size=20 AS SELECT * FROM customer;
```

Now you can use *custfix* for fast database operations on the copied_customer_ table data.

Retrieving data from a spreadsheet

ODBC can also be used to create tables based on tabular data belonging to an
Excel spreadsheet:

```
CREATE TABLE XLCONT
ENGINE=CONNECT table_type=ODBC tabname='CONTACT'
CONNECTION='DSN=Excel Files;DBQ=D:/Ber/Doc/Contact_BP.xls;';
```

This supposes that a tabular zone of the sheet including column headers is defined as a table named CONTACT or using a “named reference”. Refer to the Excel documentation for how to specify tables inside sheets. Once done, you can ask:

```
SELECT * FROM xlcont;
```

This will extract the data from Excel and display:

Nom	Function	Societe
Boisseau Frederic		9 Telecom
Martelliere Nicolas		Vidal SA (Groupe UBM)
Remy Agathe		Price Minister
Du Halgouet Tanguy		Danone
Vandamme Anna		GDF
Thomas Willy		Europ Assistance France
Thomas Dominique		Acoss (DG des URSSAF)
Thomas Berengere	Responsible SI Decisionnel	DEXIA Credit Local
Husy Frederic	Responsible Decisionnel	Neuf Cegetel
Lemonnier Nathalie	Directeur Marketing Client	Louis Vuitton
Louis Loic	Reporting International Decisionnel	Accor
Menseau Eric		Orange France

Here again, the columns description was left to CONNECT when creating the table.

Multiple ODBC tables

The concept of multiple tables can be extended to ODBC tables when they are physically represented by files, for instance to Excel or Access tables. The condition is that the connect string for the table must contain a field DBQ=*filename*, in which wildcard characters can be included as for multiple=1 tables in their filename. For instance, a table contained in several
Excel files CA200401.xls, CA200402.xls, …CA200412.xls can be created by a command such as:

```
CREATE TABLE ca04mul (DATE CHAR(19), OPERATION VARCHAR(64),
  Debit DOUBLE(15,2), Credit DOUBLE(15,2))
ENGINE=CONNECT table_type=ODBC multiple=1
qchar= '"' tabname='bank account'
CONNECTION='DSN=Excel Files;DBQ=D:/Ber/CA/CA2004*.xls;';
```

Providing that in each file the applying information is internally set for
Excel as a table named “bank account”. This extension to ODBC does not support_multiple_=2. The *qchar* option was specified to make the identifiers quoted in the select statement sent to ODBC, in particular the when the table or column names contain blanks, to avoid SQL syntax errors.

Caution: Avoid accessing tables belonging to the currently running MariaDB server via the MySQL ODBC connector. This may not work and may cause the server to be restarted.

Performance consideration

To avoid extracting entire tables from an ODBC source, which can be a lengthy process, CONNECT extracts the “compatible” part of query WHERE clauses and adds it to the ODBC query. Compatible means that it must be understood by the data source. In particular, clauses involving scalar functions are not kept because the data source may have different functions than MariaDB or use a different syntax. Of course, clauses involving sub-select are also skipped. This will transfer eventual indexing to the data source.

Take care with clauses involving string items because you may not know whether they are treated by the data source as case sensitive or case insensitive. If in doubt, make your queries as if the data source was processing strings as case sensitive to avoid incomplete results.

Using ODBC Tables inside correlated sub-queries

Unlike not correlated subqueries that are executed only once, correlated subqueries are executed many times. It is what ODBC calls a “requery”. Several methods can be used by CONNECT to deal with this depending on the setting of the MEMORY or SCROLLABLE Boolean options:

Option	Description
Default	Implementing “requery” by discarding the current result set and re submitting the query (as MFC does)
Memory=1 or 2	Storing the result set in memory as MYSQL tables do.
Scrollable=Yes	Using a scrollable cursor.

Note: the MEMORY and SCROLLABLE options must be specified in the OPTION _ LIST.

Because the table is accessed several times, this can make queries last very long except for small tables and is almost unacceptable for big tables. However, if it cannot be avoided, using the memory method is the best choice and can be more than four times faster than the default method. If it is supported by the driver, using a scrollable cursor is slightly slower than using memory but can be an alternative to avoid memory problems when the sub-query returns a huge result set.

If the result set is of reasonable size, it is also possible to specify the block_size option equal or slightly larger than the result set. The whole result set being read on the first fetch, can be accessed many times without having to do anything else.

Another good workaround is to replace within the correlated sub-query the ODBC table by a local copy of it because MariaDB is often able to optimize the query and to provide a very fast execution.

Accessing specified views

Instead of specifying a source table name via the TABNAME option, it is possible to retrieve data from a “view” whose definition is given in a new option SRCDEF. For instance:

```
CREATE TABLE custnum (
  country VARCHAR(15) NOT NULL,
  customers INT(6) NOT NULL)
ENGINE=CONNECT TABLE_TYPE=ODBC BLOCK_SIZE=10
CONNECTION='DSN=MS Access Database;DBQ=C:/Program Files/Microsoft Office/Office/1033/FPNWIND.MDB;'
SRCDEF='select country, count(*) as customers from customers group by country';
```

Or simply, because CONNECT can retrieve the returned column definition:

```
CREATE TABLE custnum ENGINE=CONNECT TABLE_TYPE=ODBC BLOCK_SIZE=10
CONNECTION='DSN=MS Access Database;DBQ=C:/Program Files/Microsoft Office/Office/1033/FPNWIND.MDB;'
SRCDEF='select country, count(*) as customers from customers group by country';
```

Then, when executing for instance:

```
SELECT * FROM custnum WHERE customers > 3;
```

The processing of the group by is done by the data source, which returns only the generated result set on which only the where clause is performed locally.
The result:

country	customers
Brazil	9
France	11
Germany	11
Mexico	5
Spain	5
UK	7
USA	13
Venezuela	4

This makes possible to let the data source do complicated operations, such as joining several tables or executing procedures returning a result set. This minimizes the data transfer through ODBC.

Data Modifying Operations

The only data modifying operations are the INSERT , UPDATE and DELETE commands.
They can be executed successfully only if the data source database or tables are not read/only.

INSERT Command

When inserting values to an ODBC table, local values are used and sent to the ODBC table. This does not make any difference when the values are constant but in a query such as:

```
INSERT INTO t1 SELECT * FROM t2;
```

Where t1 is an ODBC table, t2 is a locally defined table that must exist on the local server. Besides, it is a good way to create a distant ODBC table from local data.

CONNECT does not directly support INSERT commands such as:

```
INSERT INTO t1 VALUES(2,'Deux') ON duplicate KEY UPDATE msg = 'Two';
```

Sure enough, the “on duplicate key update” part of it is ignored, and will result in error if the key value is duplicated.

UPDATE and DELETE Commands

Unlike the INSERT command, UPDATE and DELETE are supported in a simplified way. Only simple table commands are supported; CONNECT does not support multi-table commands, commands sent from a procedure, or issued via a trigger.

These commands are just rephrased to correspond to the data source syntax and sent to the data source for execution. Let us suppose we created the table:

```
CREATE TABLE tolite (
  id INT(9) NOT NULL,
  nom VARCHAR(12) NOT NULL,
  nais DATE DEFAULT NULL,
  rem VARCHAR(32) DEFAULT NULL)
ENGINE=CONNECT TABLE_TYPE=ODBC tabname='lite'
CONNECTION='DSN=SQLite3 Datasource;Database=test.sqlite3'
CHARSET=utf8 DATA_CHARSET=utf8;
```

We can populate it by:

```
INSERT INTO tolite VALUES(1,'Toto',NOW(),'First'),
(2,'Foo','2012-07-14','Second'),(4,'Machin','1968-05-30','Third');
```

The function `now()` are executed by MariaDB and it returned value sent to the ODBC table.

Let us see what happens when updating the table. If we use the query:

```
UPDATE tolite SET nom = 'Gillespie' WHERE id = 10;
```

CONNECT will rephrase the command as:

```
UPDATE lite SET nom = 'Gillespie' WHERE id = 10;
```

What it did is just to replace the local table name with the remote table name and change all the back ticks to blanks or to the data source identifier quoting characters if QUOTED is specified.
Then this command are sent to the data source to be executed by it.

This is simpler and can be faster than doing a positional update using a cursor and commands such as “select … for update of …” that are not supported by all data sources. However, there are some restrictions that must be understood due to the way it is handled by MariaDB.

1. MariaDB does not know about all the above. The command are parsed as if it were to be executed locally. Therefore, it must respect the MariaDB syntax.
2. Being executed by the data source, the (rephrased) command must also respect the data source syntax.
3. All data referenced in the SET and WHERE clause belongs to the data source.

This is possible because both MariaDB and the data source are using the SQL language. But you must use only the basic features that are part of the core
SQL language. For instance, keywords like IGNORE or LOW_PRIORITY will cause syntax error with many data source.

Scalar function names also can be different, which severely restrict the use of them. For instance:

```
UPDATE tolite SET nais = NOW() WHERE id = 2;
```

This will not work with SQLite3, the data source returning an “unknown scalar function” error message. Note that in this particular case, you can rephrase it to:

```
UPDATE tolite SET nais = DATE('now') WHERE id = 2;
```

This understood by both parsers, and even if this function would return NULL executed by MariaDB, it does return the current date when executed by SQLite3.
But this begins to become too trickery so to overcome all these restrictions, and permit to have all types of commands executed by the data source, CONNECT provides a specific ODBC table subtype described now.

Sending commands to a Data Source

This can be done using a special subtype of ODBC table. Let us see this in an example:

```
CREATE TABLE crlite (
  command VARCHAR(128) NOT NULL,
  NUMBER INT(5) NOT NULL flag=1,
  message VARCHAR(255) flag=2)
ENGINE=CONNECT table_type=odbc
CONNECTION='Driver=SQLite3 ODBC Driver;Database=test.sqlite3;NoWCHAR=yes'
option_list='Execsrc=1';
```

The key points in this create statement are the EXECSRC option and the column definition.

The EXECSRC option tells that this table are used to send a command to the data source. Most of the sent commands do not return result set. Therefore, the table columns are used to specify the command to be executed and to get the result of the execution. The name of these columns can be chosen arbitrarily, their function coming from the FLAG value:

Flag=0:	The command to execute.
Flag=1:	The affected rows, or -1 in case of error, or the result number of column if the command returns a result set.
Flag=2:	The returned (eventually error) message.

How to use this table and specify the command to send? By executing a command such as:

```
SELECT * FROM crlite WHERE command = 'a command';
```

This will send the command specified in the WHERE clause to the data source and return the result of its execution. The syntax of the WHERE clause must be exactly as shown above. For instance:

```
SELECT * FROM crlite WHERE command =
'CREATE TABLE lite (
ID integer primary key autoincrement,
name char(12) not null,
birth date,
rem varchar(32))';
```

This command returns:

command	number	message
CREATE TABLE lite (ID integer primary key autoincrement, name…	0	Affected rows

Now we can create a standard ODBC table on the newly created table:

```
CREATE TABLE tlite
ENGINE=CONNECT TABLE_TYPE=ODBC tabname='lite'
CONNECTION='Driver=SQLite3 ODBC Driver;Database=test.sqlite3;NoWCHAR=yes'
CHARSET=utf8 DATA_CHARSET=utf8;
```

We can populate it directly using the supported INSERT statement:

```
INSERT INTO tlite(name,birth) VALUES('Toto','2005-06-12');
INSERT INTO tlite(name,birth,rem) VALUES('Foo',NULL,'No ID');
INSERT INTO tlite(name,birth) VALUES('Truc','1998-10-27');
INSERT INTO tlite(name,birth,rem) VALUES('John','1968-05-30','Last');
```

And see the result:

```
SELECT * FROM tlite;
```

ID	name	birth	rem
1	Toto	2005-06-12	NULL
2	Foo	NULL	No ID
3	Truc	1998-10-27	NULL
4	John	1968-05-30	Last

Any command, for instance UPDATE, can be executed from the *crlite* table:

```
SELECT * FROM crlite WHERE command =
'update lite set birth = ''2012-07-14'' where ID = 2';
```

This command returns:

command	number	message
update lite set birth = '2012-07-15' where ID = 2	1	Affected rows

Let us verify it:

```
SELECT * FROM tlite WHERE ID = 2;
```

ID	name	birth	rem
2	Foo	2012-07-15	No ID

The syntax to send a command is rather strange and may seem unnatural. It is possible to use an easier syntax by defining a stored procedure such as:

```
CREATE PROCEDURE send_cmd(cmd VARCHAR(255))
MODIFIES SQL DATA
SELECT * FROM crlite WHERE command = cmd;
```

Now you can send commands like this:

```
call send_cmd('drop tlite');
```

This is possible only when sending one single command.

Sending several commands together

Grouping commands uses an easier syntax and is faster because only one connection is made for the all of them. To send several commands in one call, use the following syntax:

```
SELECT * FROM crlite WHERE command IN (
  'update lite set birth = ''2012-07-14'' where ID = 2',
  'update lite set birth = ''2009-08-10'' where ID = 3');
```

When several commands are sent, the execution stops at the end of them or after a command that is in error. To continue after *n* errors, set the option maxerr=*n* (0 by default) in the option list.

Note 1: It is possible to specify the SRCDEF option when creating an EXECSRC table. It are the command sent by default when a WHERE clause is not specified.

Note 2: Most data sources do not allow sending several commands separated by semi-colons.

Note 3: Quotes inside commands must be escaped. This can be avoided by using a different quoting character than the one used in the command

Note 4: The sent command must obey the data source syntax.

Note 5: Sent commands apply in the specified database. However, they can address any table within this database, or belonging to another database using the name syntax *schema.tabname*.

Connecting to a Data Source

There are two ways to establish a connection to a data source:

1. Using SQLDriverConnect and a Connection String
2. Using SQLConnect and a Data Source Name (DSN)

The first way uses a Connection String whose components describe what is needed to establish the connection. It is the most complete way to do it and by default CONNECT uses it.

The second way is a simplified way in which ODBC is just given the name of a DSN that must have been defined to ODBC or UnixOdbc and that contains the necessary information to establish the connection. Only the user name and password can be specified out of the DSN specification.

Defining the Connection String

Using the first way, the connection string must be specified. This is sometimes the most difficult task when creating ODBC tables because, depending on the operating system and the data source, this string can widely differ.

The format of the ODBC Connection String is:

```
connection-string::= empty-string[;] | attribute[;] | attribute; connection-string
empty-string ::=
attribute ::= attribute-keyword=attribute-value | DRIVER=[{]attribute-value[}]
attribute-keyword ::= DSN | UID | PWD | driver-defined-attribute-keyword
attribute-value ::= character-string
driver-defined-attribute-keyword = identifier
```

Where character-string has zero or more characters; identifier has one or more characters; attribute- keyword is not case-sensitive; attribute-value may be case-sensitive; and the value of the DSN keyword does not consist solely of blanks. Due to the connection string grammar, keywords and attribute values that contain the characters `[]{}(),;?*=!@` should be avoided. The value of the DSN keyword cannot consist only of blanks, and should not contain leading blanks. Because of the grammar of the system information, keywords and data source names cannot contain the backslash () character. Applications do not have to add braces around the attribute value after the DRIVER keyword unless the attribute contains a semicolon (;), in which case the braces are required.
If the attribute value that the driver receives includes the braces, the driver should not remove them, but they should be part of the returned connection string.

ODBC Defined Connection Attributes

The ODBC defined attributes are:

- DSN - the name of the data source to connect to. You must create this before attempting to refer to it. You create new DSNs through the ODBC Administrator (Windows), ODBCAdmin (unixODBC's GUI manager) or in the odbc.ini file.
- DRIVER - the name of the driver to connect to. You can use this in DSN-less connections.
- FILEDSN - the name of a file containing the connection attributes.
- UID/PWD - any username and password the database requires for authentication.
- SAVEFILE - request the DSN attributes are saved in this file.

Other attributes are DSN dependent attributes. The connection string can give the name of the driver in the DRIVER field or the data source in the DSN field (attention! meet the spelling and case) and has other fields that depend on

the data source. When specifying a file, the DBQ field must give the **full** path and name of the file containing the table. Refer to the specific ODBC connector documentation for the exact syntax of the connection string.

Using a Predefined DSN

This is done by specifying in the option list the Boolean option “UseDSN” as yes or 1. In addition, string options “user” and “password” can be optionally specified in the option list.

When doing so, the connection string just contains the name of the predefined Data Source. For instance:

```
CREATE TABLE tlite ENGINE=CONNECT TABLE_TYPE=ODBC tabname='lite'
CONNECTION='SQLite3 Datasource'
OPTION_LIST='UseDSN=Yes,User=me,Password=mypass';
```

Note: the connection data source name (limited to 32 characters) should not be preceded by “DSN=”.

ODBC Tables on Linux/Unix

In order to use ODBC tables, you will need to have unixODBC installed. Additionally, you will need the ODBC driver for your foreign server’s protocol. For example, for MS SQL Server or Sybase, you will need to have FreeTDS installed.

Make sure the user running mysqld (usually the mysql user) has permission to the ODBC data source configuration and the ODBC drivers.
If you get an error on Linux/Unix when using TABLE_TYPE=ODBC:

```
Error Code: 1105 [unixODBC][Driver Manager]Can't open lib
'/usr/cachesys/bin/libcacheodbc.so' : file not found
```

You must make sure that the user running mysqld (usually “mysql”) has enough permission to load the ODBC driver library. It can happen that the driver file does not have enough read privileges (use chmod to fix this), or loading is prevented by SELinux configuration (see below).

Try this command in a shell to check if the driver had enough permission:

```
sudo -u mysql ldd /usr/cachesys/bin/libcacheodbc.so
```

SELinux

SELinux can cause various problems. If you think SELinux is causing problems, check the system log (e.g. /var/log/messages) or the audit log (e.g. /var/log/audit/audit.log).

mysqld can’t load some executable code, so it can’t use the ODBC driver.

Example error:

```
Error Code: 1105 [unixODBC][Driver Manager]Can't open lib
'/usr/cachesys/bin/libcacheodbc.so' : file not found
```

Audit log:

```
type=AVC msg=audit(1384890085.406:76): avc: denied { execute }
for pid=1433 comm="mysqld"
path="/usr/cachesys/bin/libcacheodbc.so" dev=dm-0 ino=3279212
scontext=unconfined_u:system_r:mysqld_t:s0
tcontext=unconfined_u:object_r:usr_t:s0 tclass=file
```

mysqld can’t open TCP sockets on some ports, so it can’t connect to the foreign server.

Example error:

```
ERROR 1296 (HY000): Got error 174 '[unixODBC][FreeTDS][SQL Server]Unable to connect to data source' from
CONNECT
```

Audit log:

```
type=AVC msg=audit(1423094175.109:433): avc:  denied  { name_connect } for  pid=3193 comm="mysqld"
dest=1433 scontext=system_u:system_r:mysqld_t:s0 tcontext=system_u:object_r:mssql_port_t:s0
tclass=tcp_socket
```

ODBC Catalog Information

Depending on the version of the used ODBC driver, some additional information on the tables are existing, such as table QUALIFIER or OWNER for old versions, now named CATALOG or SCHEMA since version 3.

CATALOG is apparently rarely used by most data sources, but SCHEMA (formerly
OWNER) is and corresponds to the DATABASE information of MySQL.

The issue is that if no schema name is specified, some data sources return information for all schemas while some others only return the information of the “default” schema. In addition, the used “schema” or “database” is sometimes implied by the connection string and sometimes is not. Sometimes, it also can be included in a data source definition.

CONNECT offers two ways to specify this information:

1. When specified, the DBNAME create table option is regarded by ODBC tables as the SCHEMA name.
2. Table names can be specified as “cat.sch.tab” allowing to set the catalog and schema info.

When both are used, the qualified table name has precedence over DBNAME . For instance:

Tabname	DBname	Description
test.t1		The t1 table of the test schema.
test.t1	mydb	The t1 table of the test schema (test has precedence)
t1	mydb	The t1 table of the mydb schema
%.%.%		All tables in all catalogs and all schemas
t1		The t1 table in the default or all schema depending on the DSN
%.t1		The t1 table in all schemas for all DSN
test.%		All tables in the test schema

When creating a standard ODBC table, you should make sure only one source table is specified. Specifying more than one source table must be done only for
CONNECT catalog tables (with CATFUNC=tables or columns).

In particular, when column definition is left to the Discovery feature, if tables with the same name are present in several schemas and the schema name is not specified, several columns with the same name are generated. This will make the creation fail with a not very explicit error message.

Note: With some ODBC drivers, the DBNAME option or qualified table name is useless because the schema implied by the connection string or the definition of the data source has priority over the specified DBNAME .

Table name case

Another issue when dealing with ODBC tables is the way table and column names are handled regarding of the case.

For instance, Oracle follows to the SQL standard here. It converts non-quoted identifiers to upper case. This is correct and expected. PostgreSQL is not standard. It converts identifiers to lower case. MySQL/MariaDB is not

standard. They preserve identifiers on Linux, and convert to lower case on Windows.

Think about that if you fail to see a table or a column on an ODBC data source.

Non-ASCII Character Sets with Oracle

When connecting through ODBC, the MariaDB Server operates as a client to the foreign database management system. As such, it requires that you configure MariaDB as you would configure native clients for the given database server.

In the case of connecting to Oracle, when using non-ASCI character sets, you need to properly set the NLS_LANG environment variable before starting the MariaDB Server.

For instance, to test this on Oracle, create a table that contains a series of special characters:

```
CREATE TABLE t1 (letter VARCHAR(4000));

INSERT INTO t1 VALUES
   (UTL_RAW.CAST_TO_VARCHAR2(HEXTORAW('C4'))),
   (UTL_RAW.CAST_TO_VARCHAR2(HEXTORAW('C5'))),
   (UTL_RAW.CAST_TO_VARCHAR2(HEXTORAW('C6')));

SELECT letter, RAWTOHEX(letter) FROM t1;

letter | RAWTOHEX(letter)
-------|-----------------
Ä      | C4
Å      | C5
Æ      | C6
```

Then create a connecting table on MariaDB and attempt the same query:

```
CREATE TABLE t1 (
   letter VARCHAR(4000))
ENGINE=CONNECT
DEFAULT CHARSET=utf8mb4
CONNECTION='DSN=YOUR_DSN'
TABLE_TYPE = 'ODBC'
DATA_CHARSET = latin1
TABNAME = 'YOUR_SCHEMA.T1';

SELECT letter, HEX(letter) FROM t1;

+--------+-------------+
| letter | HEX(letter) |
+--------+-------------+
| A      |      41 |
| ?      |      3F |
| ?      |      3F |
+--------+-------------+
```

While the character set is defined in a way that satisfies MariaDB, it has not been defined for Oracle, (that is, setting the NLS_LANG environment variable). As a result, Oracle is not providing the characters you want to MariaDB and Connect.
The specific method of setting the NLS_LANG variable can vary depending on your operating system or distribution. If you're experiencing this issue, check your OS documentation for more details on how to properly set environment variables.

Using systemd

With Linux distributions that use systemd, you need to set the environment variable in the service file, (systemd doesn't read from the /etc/environment file).

This is done by setting the Environment variable in the [Service] unit. For instance,

```
# systemctl edit mariadb.service

[Service]
Environment=NLS_LANG=GERMAN_GERMANY.WE8ISO8859P1
```

Then restart MariaDB,

```
# systemctl restart mariadb.service
```

You can now retrieve the appropriate characters from Oracle tables:

```
SELECT letter, HEX(letter) FROM t1;

+--------+-------------+
| letter | HEX(letter) |
+--------+-------------+
| Ä      | C384        |
| Å      | C385        |
| Æ      | C386        |
+--------+-------------+
```

Using Windows

Microsoft Windows doesn't ignore environment variables the way systemd does on Linux, but it does require that you set the NLS_LANG environment variable on your system. In order to do so, you need to open an elevated command-prompt, (that is, Cmd.exe with administrative privileges).

From here, you can use the Setx command to set the variable. For instance,

```
Setx NLS_LANG GERMAN_GERMANY.WE8ISO8859P1 /m
```

Note: For more detail about this, see MDEV-17501.

`OPTION_LIST` Values Supported by the ODBC Tables

The following options can be given as comma-separated string to the `OPTION_LIST` value in the `CREATE TABLE` statement.

Name	Default	Description
MaxRes	0	Maximum number of rows returned by catalog functions
ConnectTimeout	-1	Connection timeout in seconds, unlimited by default
QueryTimeout	-1	Query timeout in seconds, unlimited by default
UseDSN	false	Use pre-configured DSN

This page is licensed: GPLv2

CONNECT PIVOT Table Type

This table type can be used to transform the result of another table or view (called the source table) into a pivoted table along "pivot" and "facts" columns. A pivot table is a great reporting tool that sorts and sums (by default) independent of the original data layout in the source table.

For example, let us suppose you have the following “Expenses” table:

Who	Week	What	Amount
Joe	3	Beer	18.00
Beth	4	Food	17.00
Janet	5	Beer	14.00
Joe	3	Food	12.00
Joe	4	Beer	19.00
Janet	5	Car	12.00
Joe	3	Food	19.00
Beth	4	Beer	15.00
Janet	5	Beer	19.00
Joe	3	Car	20.00
Joe	4	Beer	16.00
Beth	5	Food	12.00
Beth	3	Beer	16.00
Joe	4	Food	17.00
Joe	5	Beer	14.00
Janet	3	Car	19.00
Joe	4	Food	17.00
Beth	5	Beer	20.00
Janet	3	Food	18.00
Joe	4	Beer	14.00
Joe	5	Food	12.00
Janet	3	Beer	18.00
Janet	4	Car	17.00
Janet	5	Food	12.00

Pivoting the table contents using the ‘Who’ and ‘Week’ fields for the left columns, and the ‘What’ field for the top heading and summing the ‘Amount’ fields for each cell in the new table, gives the following desired result:

Who	Week	Beer	Car	Food
Beth	3	16.00	0.00	0.00
Beth	4	15.00	0.00	17.00
Beth	5	20.00	0.00	12.00
Janet	3	18.00	19.00	18.00
Janet	4	0.00	17.00	0.00
Janet	5	33.00	12.00	12.00
Joe	3	18.00	20.00	31.00
Joe	4	49.00	0.00	34.00
Joe	5	14.00	0.00	12.00

Note that SQL enables you to get the same result presented differently by using the “group by” clause, namely:

```
SELECT who, week, what, SUM(amount) FROM expenses
       GROUP BY who, week, what;
```

However there is no way to get the pivoted layout shown above just using SQL.
Even using embedded SQL programming for some DBMS is not quite simple and automatic.

The Pivot table type of CONNECT makes doing this much simpler.

Using the PIVOT Tables Type

To get the result shown in the example above, just define it as a new table with the statement:

```
CREATE TABLE pivex
ENGINE=connect table_type=pivot tabname=expenses;
```

You can now use it as any other table, for instance to display the result shown above, just say:

```
SELECT * FROM pivex;
```

The CONNECT implementation of the PIVOT table type does much of the work required to transform the source table:

1. Finding the “Facts” column, by default the last column of the source table. Finding “Facts” or “Pivot” columns work only for table based pivot tables. They do not for view or srcdef based pivot tables, for which they must be explicitly specified.
2. Finding the “Pivot” column, by default the last remaining column.
3. Choosing the aggregate function to use, “SUM” by default.
4. Constructing and executing the “Group By” on the “Facts” column, getting its result in memory.
5. Getting all the distinct values in the “Pivot” column and defining a “Data” column for each.
6. Spreading the result of the intermediate memory table into the final table.

The source table “Pivot” column must not be nullable (there are no such things as a “null” column) The creation are refused even is this nullable column actually does not contain null values.

If a different result is desired, Create Table options are available to change the defaults used by Pivot. For instance if we want to display the average expense for each person and product, spread in columns for each week, use the following statement:

```
CREATE TABLE pivex2
ENGINE=connect table_type=pivot tabname=expenses
option_list='PivotCol=Week,Function=AVG';
```

Now saying:

```
SELECT * FROM pivex2;
```

Will display the resulting table:

Who	What	3	4	5
Beth	Beer	16.00	15.00	20.00
Beth	Food	0.00	17.00	12.00
Janet	Beer	18.00	0.00	16.50
Janet	Car	19.00	17.00	12.00
Janet	Food	18.00	0.00	12.00

Who	What	3	4	5
Joe	Beer	18.00	16.33	14.00
Joe	Car	20.00	0.00	0.00
Joe	Food	15.50	17.00	12.00

Restricting the Columns in a Pivot Table

Let us suppose that we want a Pivot table from expenses summing the expenses for all people and products whatever week it was bought. We can do this just by removing from the pivex table the week column from the column list.

```
ALTER TABLE pivex DROP COLUMN week;
```

The result we get from the new table is:

Who	Beer	Car	Food
Beth	51.00	0.00	29.00
Janet	51.00	48.00	30.00
Joe	81.00	20.00	77.00

Note: Restricting columns is also needed when the source table contains extra columns that should not be part of the pivot table. This is true in particular for key columns that prevent a proper grouping.

PIVOT Create Table Syntax

The Create Table statement for PIVOT tables uses the following syntax:

```
CREATE TABLE pivot_table_name
[(column_definition)]
ENGINE=CONNECT table_type=PIVOT
{tabname='source_table_name' | srcdef='source_table_def'}
[option_list='pivot_table_option_list'];
```

The column definition has two sets of columns:

1. A set of columns belonging to the source table, not including the “facts” and “pivot” columns.
2. “Data” columns receiving the values of the aggregated “facts” columns named from the values of the “pivot” column. They are indicated by the “flag” option.

The **options** and **sub-options** available for Pivot tables are:

Option	Type	Description
Tabname	[DB.]Name	The name of the table to “pivot”. If not set SrcDef must be specified.
SrcDef	SQL_statement	The statement used to generate the intermediate mysql table.
DBname	name	The name of the database containing the source table. Defaults to the current database.
Function*	name	The name of the aggregate function used for the data columns, SUM by default.
PivotCol*	name	Specifies the name of the Pivot column whose values are used to fill the “data” columns having the flag option.
FncCol*	[func()name[)]	Specifies the name of the data “Facts” column. If the form func(name) is used, the aggregate function name is set to func.

Option	Type	Description
Groupby *	Boolean	Set it to True (1 or Yes) if the table already has a GROUP BY format.
Accept*	Boolean	To accept non matching Pivot column values.

- : These options must be specified in the OPTION_LIST.

Additional Access Options

There are four cases where pivot must call the server containing the source table or on which the SrcDef statement must be executed:

1. The source table is not a CONNECT table.
2. The SrcDef option is specified.
3. The source table is on another server.
4. The columns are not specified.

By default, pivot tries to call the currently used server using host=localhost, user=root not using password, and port=3306. However, this may not be what is needed, in particular if the local root user has a password in which case you can get an “access denied” error message when creating or using the pivot table.

Specify the host, user, password and/or port options in the option_list to override the default connection options used to access the source table, get column specifications, execute the generated group by or SrcDef query.

Defining a Pivot Table

There are principally two ways to define a PIVOT table:

1. From an existing table or view.
2. Directly giving the SQL statement returning the result to pivot.

Defining a Pivot Table from a Source Table

The **tabname** standard table option is used to give the name of the source table or view.

For tables, the internal Group By are internally generated, except when the `GROUP BY` option is specified as true. Do it only when the table or view has a valid `GROUP BY` format.

Directly Defining the Source of a Pivot Table in SQL

Alternatively, the internal source can be directly defined using the **SrcDef** option that must have the proper group by format.

As we have seen above, a proper Pivot Table is made from an internal intermediate table resulting from the execution of a `GROUP BY` statement. In many cases, it is simpler or desirable to directly specify this when creating the pivot table. This may be because the source is the result of a complex process including filtering and/or joining tables.

To do this, use the **SrcDef** option, often replacing all other options. For instance, suppose that in the first example we are only interested in weeks 4 and 5. We could of course display it by:

```
SELECT * FROM pivex WHERE week IN (4,5);
```

However, what if this table is a huge table? In this case, the correct way to do it is to define the pivot table as this:

```
CREATE TABLE pivex4
ENGINE=connect table_type=pivot
option_list='PivotCol=what,FncCol=amount'
SrcDef='select who, week, what, sum(amount) from expenses
where week in (4,5) group by who, week, what';
```

If your source table has millions of records and you plan to pivot only a small subset of it, doing so will make a lot of a difference performance wise. In addition, you have entire liberty to use expressions, scalar functions, aliases, join, where and having clauses in your SQL statement. The only constraint is that you are responsible for the result of this statement to have the correct format for the pivot processing.

Using SrcDef also permits to use expressions and/or scalar functions. For instance:

```
CREATE TABLE xpivot (
Who CHAR(10) NOT NULL,
What CHAR(12) NOT NULL,
First DOUBLE(8,2) flag=1,
Middle DOUBLE(8,2) flag=1,
Last DOUBLE(8,2) flag=1)
ENGINE=connect table_type=PIVOT
option_list='PivotCol=wk,FncCol=amnt'
Srcdef='select who, what, case when week=3 then ''First'' when
week=5 then ''Last'' else ''Middle'' end as wk, sum(amount) *
6.56 as amnt from expenses group by who, what, wk';
```

Now the statement:

```
SELECT * FROM xpivot;
```

Will display the result:

Who	What	First	Middle	Last
Beth	Beer	104.96	98.40	131.20
Beth	Food	0.00	111.52	78.72
Janet	Beer	118.08	0.00	216.48
Janet	Car	124.64	111.52	78.72
Janet	Food	118.08	0.00	78.72
Joe	Beer	118.08	321.44	91.84
Joe	Car	131.20	0.00	0.00
Joe	Food	203.36	223.04	78.72

Note 1: to avoid multiple lines having the same fixed column values, it is mandatory in **SrcDef** to place the pivot column at the end of the group by list.

Note 2: in the create statement **SrcDef**, it is mandatory to give aliases **to** the columns containing expressions so they are recognized by the other options.

Note 3: in the **SrcDef** select statement, quotes must be escaped because the entire statement is passed to MariaDB between quotes. Alternatively, specify it between double quotes.

Note 4: We could have left CONNECT do the column definitions. However, because they are defined from the sorted names, the Middle column had been placed at the end of them.

Specifying the Columns Corresponding to the Pivot Column

These columns must be named from the values existing in the “pivot” column. For instance, supposing we have the following *pet* table:

name	race	number
John	dog	2
Bill	cat	1
Mary	dog	1
Mary	cat	1
Lisbeth	rabbit	2
Kevin	cat	2
Kevin	bird	6
Donald	dog	1
Donald	fish	3

Pivoting it using *race* as the pivot column is done with:

```
CREATE TABLE pivet
ENGINE=connect table_type=pivot tabname=pet
option_list='PivotCol=race,groupby=1';
```

This gives the result:

name	dog	cat	rabbit	bird	fish
John	2	0	0	0	0
Bill	0	1	0	0	0
Mary	1	1	0	0	0
Lisbeth	0	0	2	0	0
Kevin	0	2	0	6	0
Donald	1	0	0	0	3

By the way, does this ring a bell? It shows that in a way PIVOT tables are doing the opposite of what OCCUR tables do.

We can alternatively define specifically the table columns but what happens if the Pivot column contains values that is not matching a “data” column? There are three cases depending on the specified options and flags.

First case: If no specific options are specified, this is an error an when trying to display the table. The query will abort with an error message stating that a non-matching value was met. Note that because the column list is established when creating the table, this is prone to occur if some rows containing new values for the pivot column are inserted in the source table. If this happens, you should re-create the table or manually add the new columns to the pivot table.

Second case: The accept option was specified. For instance:

```
CREATE TABLE xpivet2 (
name VARCHAR(12) NOT NULL,
dog INT NOT NULL DEFAULT 0 flag=1,
cat INT NOT NULL DEFAULT 0 flag=1)
ENGINE=connect table_type=pivot tabname=pet
option_list='PivotCol=race,groupby=1,Accept=1';
```

No error are raised and the non-matching values are ignored. This table are displayed as:

name	dog	cat
John	2	0

name	dog	cat
Bill	0	1
Mary	1	1
Lisbeth	0	0
Kevin	0	2
Donald	1	0

Third case: A “dump” column was specified with the flag value equal to 2. All non-matching values are added in this column. For instance:

```
CREATE TABLE xpivet (
name VARCHAR(12) NOT NULL,
dog INT NOT NULL DEFAULT 0 flag=1,
cat INT NOT NULL DEFAULT 0 flag=1,
other INT NOT NULL DEFAULT 0 flag=2)
ENGINE=connect table_type=pivot tabname=pet
option_list='PivotCol=race,groupby=1';
```

This table are displayed as:

name	dog	cat	other
John	2	0	0
Bill	0	1	0
Mary	1	1	0
Lisbeth	0	0	2
Kevin	0	2	6
Donald	1	0	3

It is a good idea to provide such a “dump” column if the source table is prone to be inserted new rows that can have a value for the pivot column that did not exist when the pivot table was created.

Pivoting Big Source Tables

This may sometimes be risky. If the pivot column contains too many distinct values, the resulting table may have too many columns. In all cases the process involved, finding distinct values when creating the table or doing the group by when using it, can be very long and sometimes can fail because of exhausted memory.

Restrictions by a where clause should be applied to the source table when creating the pivot table rather than to the pivot table itself. This can be done by creating an intermediate table or using as source a view or a srcdef option.

All PIVOT tables are read only.

This page is licensed: CC BY-SA / Gnu FDL

CONNECT PROXY Table Type

A `PROXY` table is a table that accesses and reads the data of another table or view. To create a table based on the boys `FIX` table:

```
CREATE TABLE xboy ENGINE=CONNECT
  table_type=PROXY tabname=boys;
```

Simply, `PROXY` being the default type when `TABNAME` is specified:

```
CREATE TABLE xboy ENGINE=CONNECT tabname=boys;
```

Because the boys table can be directly used, what can be the use of a proxy table? Well, its main use is to be internally used by other table types such as TBL, XCOL, OCCUR, or PIVOT. Sure enough, PROXY tables are CONNECT tables, meaning that they can be based on tables of any engines and accessed by table types that need to access CONNECT tables.

Proxy on non-CONNECT Tables

When the sub-table is a view or not a CONNECT table, CONNECT internally creates a temporary CONNECT table of MYSQL type to access it. This connection uses the same default parameters as for a `MYSQL` table. It is also possible to specify them to the `PROXY` table using in the `PROXY` declaration the same `OPTION_LIST` options as for a `MYSQL` table. Of course, it is simpler and more natural to use directly the MYSQL type in this case.

Normally, the default parameters should enable the `PROXY` table to reconnect the server. However, an issue is when the current user was logged using a password. The security protocol prevents CONNECT to retrieve this password and requires it to be given in the `PROXY` table create statement. For instance adding to it:

```
... option_list='Password=mypass';
```

However, it is often not advisable to write in clear a password that can be seen by all user able to see the table declaration by show create table, in particular, if the table is used when the current user is root. To avoid this, a specific user should be created on the local host that are used by proxy tables to retrieve local tables. This user can have minimum grant options, for instance `SELECT` on desired directories, and needs no password. Supposing 'proxy' is such a user, the option list to add are:

```
... option_list='user=proxy';
```

Using a PROXY Table as a View

A `PROXY` table can also be used by itself to modify the way a table is viewed. For instance, a proxy table does not use the indexes of the object table. It is also possible to define its columns with different names or type, to use only some of them or to changes their order. For instance:

```
CREATE TABLE city (
  city VARCHAR(11),
  boy CHAR(12) flag=1,
  birth DATE)
ENGINE=CONNECT tabname=boys;
SELECT * FROM city;
```

This displays:

city	boy	birth
Boston	John	1986-01-25
Boston	Henry	1987-06-07
San Jose	George	1981-08-10
Chicago	Sam	1979-11-22
Dallas	James	1992-05-13
Boston	Bill	1986-09-11

Here we did not have to specify column format or offset because data are retrieved from the boys table, not directly from the boys.txt file. The flag option of the *boy* column indicates that it correspond to the first column of the boys table, the *name* column.

Avoiding PROXY Table Loop

CONNECT is able to test whether a `PROXY`, or `PROXY`-based, table refers directly or indirectly to itself. If a direct reference can tested at table creation, an indirect reference can only be tested when executing a query on the table. However, this is possible only for local tables. When using remote tables or views, a problem can occur if the remote table or the view refers back to one of the local tables of the chain. The same caution should be used than when using FEDERATEDX tables.

Note: All `PROXY` or `PROXY`-based tables are read-only in this version.

Modifying Operations

All INSERT / UPDATE / DELETE operations can be used with proxy tables. However, the same restrictions applying to the source table also apply to the proxy table.

Note: All PROXY and PROXY-based table types are not indexable.

This page is licensed: CC BY-SA / Gnu FDL

CONNECT Table Types - Catalog Tables

A catalog table is one that returns information about another table, or data source. It is similar to what MariaDB commands such as `DESCRIBE` or `SHOW` do. Applied to local tables, this just duplicates what these commands do, with the noticeable difference that they are tables and can be used inside queries as joined tables or inside sub-selects.

But their main interest is to enable querying the structure of external tables that cannot be directly queried with description commands. Let's see an example:

Suppose we want to access the tables from a Microsoft Access database as an ODBC type table. The first information we must obtain is the list of tables existing in this data source. To get it, we will create a catalog table that will return it extracted from the result set of the SQLTables ODBC function:

```
CREATE TABLE tabinfo (
  table_name VARCHAR(128) NOT NULL,
  table_type VARCHAR(16) NOT NULL)
ENGINE=CONNECT table_type=ODBC catfunc=TABLES
CONNECTION='DSN=MS Access Database;DBQ=C:/Program
Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

The SQLTables function returns a result set having the following columns:

Field	Data Type	Null	Info Type	Flag Value
Table_Cat	char(128)	NO	FLD_CAT	17
Table_Name	char(128)	NO	FLD_SCHEM	18
Table_Name	char(128)	NO	FLD_NAME	1
Table_Type	char(16)	NO	FLD_TYPE	2
Remark	char(128)	NO	FLD_REM	5

Note: The Info Type and Flag Value are CONNECT interpretations of this result.

Here we could have omitted the column definitions of the catalog table or, as in the above example, chose the columns returning the name and type of the tables. If specified, the columns must have the exact name of the corresponding SQLTables result set, or be given a different name with the matching flag value specification.

(The Table_Type can be TABLE, SYSTEM TABLE, VIEW, etc.)

For instance, to get the tables we want to use we can ask:

```
SELECT TABLE_NAME FROM tabinfo WHERE table_type = 'TABLE';
```

This will return:

table_name
Categories
Customers
Employees
Products
Shippers
Suppliers

Now we want to create the table to access the CUSTOMERS table. Because CONNECT can retrieve the column description of ODBC tables, it not necessary to specify them in the create table statement:

```
CREATE TABLE Customers ENGINE=CONNECT table_type=ODBC
CONNECTION='DSN=MS Access Database;DBQ=C:/Program
Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

However, if we prefer to specify them (to eventually modify them) we must know what the column definitions of that table are. We can get this information with a catalog table. This is how to do it:

```
CREATE TABLE custinfo ENGINE=CONNECT table_type=ODBC
tabname=customers catfunc=columns
CONNECTION='DSN=MS Access Database;DBQ=C:/Program
Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

Alternatively it is possible to specify what columns of the catalog table we want:

```
CREATE TABLE custinfo (
  column_name CHAR(128) NOT NULL,
  type_name CHAR(20) NOT NULL,
  LENGTH INT(10) NOT NULL flag=7,
  prec SMALLINT(6) NOT NULL flag=9)
  NULLABLE SMALLINT(6) NOT NULL)
ENGINE=CONNECT table_type=ODBC tabname=customers
catfunc=columns
CONNECTION='DSN=MS Access Database;DBQ=C:/Program
Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

To get the column info:

```
SELECT * FROM custinfo;
```

which results in this table:

column_name	type_name	length	prec	nullable
CustomerID	VARCHAR	5	0	1
CompanyName	VARCHAR	40	0	1
ContactName	VARCHAR	30	0	1
ContactTitle	VARCHAR	30	0	1
Address	VARCHAR	60	0	1
City	VARCHAR	15	0	1
Region	VARCHAR	15	0	1

column_name	type_name	length	prec	nullable
PostalCode	VARCHAR	10	0	1
Country	VARCHAR	15	0	1
Phone	VARCHAR	24	0	1
Fax	VARCHAR	24	0	1

Now you can create the CUSTOMERS table as:

```
CREATE TABLE Customers (
  CustomerID VARCHAR(5),
  CompanyName VARCHAR(40),
  ContactName VARCHAR(30),
  ContactTitle VARCHAR(30),
  Address VARCHAR(60),
  City VARCHAR(15),
  Region VARCHAR(15),
  PostalCode VARCHAR(10),
  Country VARCHAR(15),
  Phone VARCHAR(24),
  Fax VARCHAR(24))
ENGINE=CONNECT table_type=ODBC block_size=10
CONNECTION='DSN=MS Access Database;DBQ=C:/Program
Files/Microsoft Office/Office/1033/FPNWIND.MDB;';
```

Let us explain what we did here: First of all, the creation of the catalog table. This table returns the result set of an ODBC SQLColumns function sent to the ODBC data source. Columns functions always return a data set having some of the following columns, depending on the table type:

Field	Data Type	Null	Info Type	Flag Value	Returned by
Table_Cat*	char(128)	NO	FLD_CAT	17	ODBC, JDBC
Table_Schema*	char(128)	NO	FLD_SCEM	18	ODBC, JDBC
Table_Name	char(128)	NO	FLD_TABNAME	19	ODBC, JDBC
Column_Name	char(128)	NO	FLD_NAME	1	ALL
Data_Type	smallint(6)	NO	FLD_TYPE	2	ALL
Type_Name	char(30)	NO	FLD_TYPENAME	3	ALL
Column_Size*	int(10)	NO	FLD_PREC	4	ALL
Buffer_Length*	int(10)	NO	FLD_LENGTH	5	ALL
Decimal_Digits*	smallint(6)	NO	FLD_SCALE	6	ALL
Radix	smallint(6)	NO	FLD_RADIX	7	ODBC, JDBC, MYSQL
Nullable	smallint(6)	NO	FLD_NULL	8	ODBC, JDBC, MYSQL
Remarks	char(255)	NO	FLD_REM	9	ODBC, JDBC, MYSQL
Collation	char(32)	NO	FLD_CHARSET	10	MYSQL
Key	char(4)	NO	FLD_KEY	11	MYSQL
Default_value	N.A.		FLD_DEFAULT	12	
Privilege	N.A.		FLD_PRIV	13	
Date_fmt	char(32)	NO	FLD_DATEFMT	15	MYSQL
Xpath/Jpath	Varchar(256)	NO	FLD_FORMAT	16	XML/JSON

‘*’: These names have changed since earlier versions of CONNECT.

Note: ALL includes the ODBC, JDBC, MYSQL, DBF, CSV, PROXY, TBL, XML, JSON, XCOL, and WMI table types. More could be added later.

We chose among these columns the ones that were useful for our create statement, using the flag value when we gave them a different name (case insensitive).

The options used in this definition are the same as the one used later for the actual CUSTOMERS data tables except that:

1. The `TABNAME` option is mandatory here to specify what the queried table name is.
2. The `CATFUNC` option was added both to indicate that this is a catalog table, and to specify that we want column information.

Note: If the `TABNAME` option had not been specified, this table would have returned the columns of all the tables defined in the connected data source.

Currently the available `CATFUNC` are:

Function	Specified as:	Applies to table types:
FNC_TAB	tables	ODBC, JDBC, MYSQL
FNC_COL	columns	ODBC, JDBC, MYSQL, DBF, CSV, PROXY, XCOL, TBL, WMI
FNC_DSN	datasourcesdsnsqldatasources	ODBC
FNC_DRIVER	driverssqldrivers	ODBC, JDBC

Note: Only the bold part of the function name specification is required.

The `DATASOURCE` and `DRIVERS` functions respectively return the list of available data sources and ODBC drivers available on the system.

The SQLDataSources function returns a result set having the following columns:

Field	Data Type	Null	Info Type	Flag value
Name	varchar(256)	NO	FLD_NAME	1
Description	varchar(256)	NO	FLD_REM	9

To get the data source, you can do for instance:

```
CREATE TABLE datasources (
ENGINE=CONNECT table_type=ODBC catfunc=DSN;
```

The SQLDrivers function returns a result set having the following columns:

Field	Type	Null	Info Type	Flag value
Description	varchar(128)	YES	FLD_NAME	1
Attributes	varchar(256)	YES	FLD_REM	9

You can get the driver list with:

```
CREATE TABLE drivers
ENGINE=CONNECT table_type=ODBC catfunc=drivers;
```

Another Example, WMI table

To create a catalog table returning the attribute names of a WMI class, use the same table options as the ones used with the normal WMI table plus the additional option ‘catfunc=columns’. If specified, the columns of such a catalog table can be chosen among the following:

Name	Type	Flag	Description
Column_Name	CHAR	1	The name of the property
Data_Type	INT	2	The SQL data type
Type_Name	CHAR	3	The SQL type name
Column_Size	INT	4	The field length in characters
Buffer_Length	INT	5	Depends on the coding
Scale	INT	6	Depends on the type

If you wish to use a different name for a column, set the Flag column option.

For example, before creating the “csprod” table, you could have created the info table:

```
CREATE TABLE CSPRODCOL (
  Column_name CHAR(64) NOT NULL,
  Data_Type INT(3) NOT NULL,
  Type_name CHAR(16) NOT NULL,
  LENGTH INT(6) NOT NULL,
  Prec INT(2) NOT NULL flag=6)
ENGINE=CONNECT table_type='WMI' catfunc=col;
```

Now the query:

```
SELECT * FROM csprodcol;
```

will display the result:

Column_name	Data_Type	Type_name	Length	Prec
Caption	1	CHAR	255	1
Description	1	CHAR	255	1
IdentifyingNumber	1	CHAR	255	1
Name	1	CHAR	255	1
SKUNumber	1	CHAR	255	1
UUID	1	CHAR	255	1
Vendor	1	CHAR	255	1
Version	1	CHAR	255	1

This can help to define the columns of the matching normal table.

Note 1: The column length, for the Info table as well as for the normal table, can be chosen arbitrarily, it just must be enough to contain the returned information.

Note 2: The Scale column returns 1 for text columns (meaning case insensitive); 2 for float and double columns; and 0 for other numeric columns.

Catalog Table result size limit

Because catalog tables are processed like the information retrieved by “Discovery” when table columns are not specified in a Create Table statement, their result set is entirely retrieved and memory allocated.

By default, this allocation is done for a maximum return line number of:

Catfunc	Max lines
Drivers	256

Catfunc	Max lines
Data Sources	512
Columns	20,000
Tables	10,000

When the number of lines retrieved for a table is more than this maximum, a warning is issued by CONNECT. This is mainly prone to occur with columns (and also tables) with some data sources having many tables when the table name is not specified.

If this happens, it is possible to increase the default limit using the MAXRES option, for instance:

```
CREATE TABLE allcols ENGINE=CONNECT table_type=odbc
CONNECTION='DSN=ORACLE_TEST;UID=system;PWD=manager'
option_list='Maxres=110000' catfunc=columns;
```

Indeed, because the entire table result is memorized before the query is executed; the returned value would be limited even on a query such as:

```
SELECT COUNT(*) FROM allcols;
```

This page is licensed: GPLv2

CONNECT Table Types - Data Files

Most of the tables processed by CONNECT are just plain DOS or UNIX data files, logically regarded as tables thanks to the description given when creating the table. This description comes from the CREATE TABLE statement. Depending on the application, these tables can already exist as data files, used as is by CONNECT, or can have been physically made by CONNECT as the result of a `CREATE TABLE ... SELECT ...` and/or INSERT statement(s).

The file *path/name* is given by the `FILE_NAME` option. If it is a relative path/name, it are relative to the database directory, the one containing the table `.FRM` file.

Unless specified, the maturity of file table types is stable.

Multiple File Tables

A **multiple** file table is one that is physically contained in several files of the same type instead of just one. These files are processed sequentially during the process of a query and the result is the same as if all the table files were merged into one. This is great to process files coming from different sources (such as cash register log files) or made at different time periods (such as bank monthly reports) regarded as one table. Note that the operations on such files are restricted to sequential Select and Update; and that VEC multiple tables are not supported by CONNECT. The file list depends on the setting of the **multiple** option of the `CREATE TABLE` statement for that table.

Multiple tables are specified by the option MULTIPLE=*n*, which can take This storage engine has been deprecated.four values:

0	Not a multiple table (the default). This can be used in an ALTER TABLE statement.
1	The table is made from files located in the same directory. The FILE_NAME option is a pattern such as ‘cash*.log’ that all the table file path/names verify.
2	The FILE_NAME gives the name of a file that contains the path/names of all the table files. This file can be made using a DIR table.
3	Like multiple=1 but also including eligible files from the directory sub-folders.

The `FILEID` special column, described here, allows query pruning by filtering the file list or doing some grouping on the files that make a multiple table.

Note: Multiple was not initially implemented for XML tables. This restriction was removed in version 1.02.

Record Format

This characteristic applies to table files handled by the operating system input/output functions. It is **fixed** for table types FIX, BIN, DBF and VEC, and it is variable for DOS, VCT, FMT and some JSON tables.

For fixed tables, most I/O operations are done by block of BLOCK_SIZE rows. This diminishes the number of I/O's and enables block indexing.

Starting with CONNECT version 1.6.6, the BLOCK_SIZE option can also be specified for variable tables. Then, a file similar to the block indexing file is created by CONNECT that gives the size in bytes of each block of BLOCK_SIZE rows. This enables the use of block I/Os and block indexing to variable tables. It also enables CONNECT to return the exact row number for info commands

File Mapping

For file-based tables of reasonable size, processing time can be greatly enhanced under Windows(TM) and some flavors of UNIX or Linux by using the technique of "file mapping", in which a file is processed as if it were entirely in memory. Mapping is specified when creating the table by the use of the `MAPPED=YES` option. This does not apply to tables not handled by system I/O functions (XML and INI).

Big File Tables

Because all files are handled by the standard input/output functions of the operating system, their size is limited to 2GB, the maximum size handled by standard functions. For some table types, CONNECT can deal with files that are larger than 2GB, or prone to become larger than this limit. These are the FIX,BIN and VEC types. To tell connect to use input/output functions dealing with big files, specify the option `huge=1` or `huge=YES` for that table. Note however that CONNECT cannot randomly access tables having more than 2G records.

Compressed File Tables

CONNECT can make and process some tables whose data file is compressed. The only supported compression format is the gzlib format. Zip and zlib formats are supported differently. The table types that can be compressed are DOS,FIX,BIN,CSV and FMT. This can save some disk space at the cost of a somewhat longer processing time.

Some restrictions apply to compressed tables:

- Compressed tables are not indexable.
- Update and partial delete are not supported.

Use the numeric compress option to specify a compressed table:

1. Not compressed
2. Compressed in gzlib format.
3. Made of compressed blocks of block_size records (enabling block indexing)

Relational Formatted Tables

These are based on files whose records represent one table row. Only the column representation within each record can differ. The following relational formatted tables are supported:

- DOS and FIX Table Types
- DBF Table Type
- BIN Table Type
- VEC Table Type
- CSV and FMT Table Types

NoSQL Table Types

These are based on files that do not match the relational format but often represent hierarchical data. CONNECT can handle JSON, INI-CFG, XML and some HTML files..

The way it is done is different from what PostgreSQL does. In addition to including in a table some column values of a specific data format (JSON, XML) to be handled by specific functions, CONNECT can directly use JSON, XML or INI files that can be produced by other applications and this is the table definition that describes where and how the contained information must be retrieved.

This is also different from what MariaDB does with dynamic columns, which is close to what MySQL and PostgreSQL do with the JSON column type.

The following NoSQL types are supported:

- XML Table Type
- JSON Table Type
- INI Table Type

This page is licensed: GPLv2

CONNECT Table Types - OEM: Implemented in an External LIB

Although CONNECT provides a rich set of table types, specific applications may need to access data organized in a way that is not handled by its existing foreign data wrappers (FDW). To handle these cases, CONNECT features an interface that enables developers to implement in C++ the required table wrapper and use it as if it were part of the standard CONNECT table type list. CONNECT can use these additional handlers providing the corresponding external module (dll or shared lib) be available.

To create such a table on an existing handler, use a Create Table statement as shown below.

```
CREATE TABLE xtab (COLUMN definitions)
ENGINE=CONNECT table_type=OEM MODULE='libname'
subtype='MYTYPE' [standard table options]
Option_list='Myopt=foo';
```

The option module gives the name of the DLL or shared library implementing the OEM wrapper for the table type. This library must be located in the plugin directory like all other plugins or UDF's.

This library must export a function *GetMYTYPE*. The option subtype enables CONNECT to have the name of the exported function and to use the new table type. Other options are interpreted by the OEM type and can also be specified within the *option_list* option.

Column definitions can be unspecified only if the external wrapper is able to return this information. For this it must export a function ColMYTYPE returning these definitions in a format acceptable by the CONNECT discovery function.

Which and how options must be specified and the way columns must be defined may vary depending on the OEM type used and should be documented by the OEM type implementer(s).

An OEM Table Example

The OEM table REST described in Adding the REST Feature as a Library Called by an OEM Table permits using REST-like tables with MariaDB binary distributions containing but not enabling the REST table type

Of course, the mongo (dll or so) exporting the GetREST and colREST functions must be available in the plugin directory for all this to work.

Some Currently Available OEM Table Modules and Subtypes

Module	Subtype	Description
libhello	HELLO	A sample OEM wrapper displaying a one line table saying “Hello world”
mongo	MONGO	Enables using tables based on MongoDB collections.
Tabfic	FIC	Handles files having the Windev HyperFile format.
Tabofx	OFC	Handles Open Financial Connectivity files.
Tabofx	QIF	Handles Quicken Interchange Format files.
Cirpack	CRPK	Handles CDR’s from Cirpack UTP’s.
Tabplg	PLG	Access tables from the PlugDB DBMS.

How to implement an OEM handler is out of the scope of this document.

This page is licensed: GPLv2

CONNECT Table Types - Special “Virtual” Tables

The special table types supported by CONNECT are the Virtual table type (VIR - introduced in MariaDB 10.0.15), Directory Listing table type (DIR), the Windows Management Instrumentation Table Type (WMI), and the “Mac Address” type (MAC).

These tables are “virtual tables”, meaning they have no physical data but rather produce result data using specific algorithms. Note that this is close to what Views are, so they could be regarded as special views.

DIR Type

A table of type DIR returns a list of file name and description as a result set. To create a DIR table, use a Create Table statement such as:

```
CREATE TABLE SOURCE (
  DRIVE CHAR(2) NOT NULL,
  PATH VARCHAR(256) NOT NULL,
  FNAME VARCHAR(256) NOT NULL,
  FTYPE CHAR(4) NOT NULL,
  SIZE DOUBLE(12,0) NOT NULL flag=5,
  MODIFIED DATETIME NOT NULL)
ENGINE=CONNECT table_type=DIR file_name='..\\*.cc';
```

When used in a query, the table returns the same file information listing than the system “DIR `*.cc`” statement would return if executed in the same current directory (here supposedly ..)

For instance, the query:

```
SELECT fname, SIZE, modified FROM SOURCE
  WHERE fname like '%handler%';
```

Displays:

fname	size	modified
handler	152177	2011-06-13 18:08:29
sql_handler	25321	2011-06-13 18:08:31

Note: the important item in this table is the flag option value (set sequentially from 0 by default) because it determines which particular information item is returned in the column:

Flag value	Information
0	The disk drive (Windows)
1	The file path
2	The file name
3	The file type
4	The file attribute
5	The file size
6	The last write access date
7	The last read access date
8	The file creation date

The Subdir option

When specified in the create table statement, the subdir option indicates to list, in addition to the files contained in the specified directory, all the files verifying the filename pattern that are contained in sub-directories of the specified directory. For instance, using:

```
CREATE TABLE DATA (
  PATH VARCHAR(256) NOT NULL flag=1,
  FNAME VARCHAR(256) NOT NULL,
  FTYPE CHAR(4) NOT NULL,
  SIZE DOUBLE(12,0) NOT NULL flag=5)
ENGINE=CONNECT table_type=DIR file_name='*.frm'
option_list='subdir=1';

SELECT PATH, COUNT(*), SUM(SIZE) FROM DATA GROUP BY PATH;
```

You will get the following result set showing how many tables are created in the MariaDB databases and what is the total length of the FRM files:

path	count(*)	sum(size)
\CommonSource\mariadb-5.2.7\sql\data\connect\	30	264469
\CommonSource\mariadb-5.2.7\sql\data\mysql\	23	207168
\CommonSource\mariadb-5.2.7\sql\data\test\	22	196882

The Nodir option (Windows)

The Boolean Nodir option can be set to false (0 or no) to add directories that match the file name pattern from the listed files (it is true by default). This is an addition to CONNECT version 1.6. Previously, directory names matching pattern were listed on Windows. Directories were and are never listed on Linux.

Note: The way file names are retrieved makes positional access to them impossible. Therefore, DIR tables cannot be indexed or sorted when it is done using positions.

Be aware, in particular when using the subdir option, that queries on DIR tables are slow and can last almost forever if made on a directory that contains a great number of files in it and its sub-directories.

dir tables can be used to populate a list of files used to create a multiple=2 table. However, this is not as useful as it was when the multiple 3 did not exist.

Windows Management Instrumentation Table Type “WMI”

Note: This table type is available on Windows only.

WMI provides an operating system interface through which instrumented components provide information. Some Microsoft tools to retrieve information through WMI are the WMIC console command and the WMI CMI Studio application.

The CONNECT WMI table type enables administrators and operators not capable of scripting or programming on top of WMI to enjoy the benefit of WMI without even learning about it. It permits to present this information as tables that can be queried, transformed, copied in documents or other tables.

To create a WMI table displaying information coming from a WMI provider, you must provide the namespace and the class name that characterize the information you want to retrieve. The best way to find them is to use the WMI CIM Studio that have tools to browse namespaces and classes and that can display the names of the properties of that class.

The column names of the tables must be the names (case insensitive) of the properties you want to retrieve. For instance:

```
CREATE TABLE ALIAS (
  friendlyname CHAR(32) NOT NULL,
  target CHAR(50) NOT NULL)
ENGINE=CONNECT table_type='WMI'
option_list='Namespace=root\\cli,Class=Msft_CliAlias';
```

WMI tables returns one row for each instance of the related information. The above example is handy to get the class equivalent of the alias of the WMIC command and also to have a list of many classes commonly used.

Because most of the useful classes belong to the ‘root\cimv2’ namespace, this is the default value for WMI tables when the namespace is not specified. Some classes have many properties whose name and type may not be known when creating the table. To find them, you can use the WMI CMI Studio application but his are rarely required because CONNECT is able to retrieve them.

Actually, the class specification also has default values for some namespaces. For the ‘root\cli’ namespace the class name defaults to ‘Msft_CliAlias’ and for the ‘root_cimv2’ namespace the class default value is ‘Win32_ComputerSystemProduct’. Because many class names begin with ‘Win32_’ it is not necessary to say it and specifying the class as ‘Product’ will effectively use class ’Win32_Product’.

For example if you define a table as:

```
CREATE TABLE CSPROD ENGINE=CONNECT table_type='WMI';
```

It will return the information on the current machine, using the class ComputerSystemProduct of the CIMV2 namespace. For instance:

```
SELECT * FROM csprod;
```

Will return a result such as:

Column	Row 1
Caption	Computer system product
Description	Computer system product
IdentifyingNumber	LXAP50X32982327A922300
Name	Aspire 8920
SKUNumber	
UUID	00FC523D-B8F7-DC12-A70E-00B0D1A46136
Vendor	Acer

Column	Row 1
Version	Aspire 8920

Note: This is a transposed display that can be obtained with some GUI.

Getting Column Information

An issue, when creating a WMI table, is to make its column definition. Indeed, even when you know the namespace and the class for the wanted information, it is not easy to find what are the names and types of its properties. However, because CONNECT can retrieve this information from the WMI provider, you can simply omit defining columns and CONNECT will do the job.

Alternatively, you can get this information using a catalog table (see below).

Performance Consideration

Some WMI providers can be very slow to answer. This is not an issue for those that return few object instances, such as the ones returning computer, motherboard, or Bios information. They generally return only one row (instance). However, some can return many rows, in particular the “CIM_DataFile” class. This is why care must be taken about them.

Firstly, it is possible to limit the allocated result size by using the ‘Estimate’ create table option. To avoid result truncation, CONNECT allocates a result of 100 rows that is enough for almost all tables.The ‘Estimate’ option permits to reduce this size for all classes that return only a few rows, and in some rare case to increase it to avoid truncation.

However, it is not possible to limit the time taken by some WMI providers to answer, in particular the CIM_DATAFILE class. Indeed the Microsoft documentation says about it:

“Avoid enumerating or querying for all instances of CIM_DataFile on a computer because the volume of data is likely to either affect performance or cause the computer to stop responding.”

Sure enough, even a simple query such as:

```
SELECT COUNT(*) FROM cim WHERE drive = 'D:' AND PATH like '\\MariaDB\\%';
```

is prone to last almost forever (probably due to the LIKE clause). This is why, when not asking for some specific items, you should consider using the DIR table type instead.

Syntax of WMI queries

Queries to WMI providers are done using the WQL language, not the SQL language. CONNECT does the job of making the WQL query. However, because of the restriction of the WQL syntax, the WHERE clause are generated only when respecting the following restrictions:

1. No function.
2. No comparison between two columns.
3. No expression (currently a CONNECT restriction)
4. No BETWEEN and IN predicates.

Filtering with WHERE clauses not respecting these conditions will still be done by MariaDB only, except in the case of CIM_Datafile class for the reason given above.

However, there is one point that is not covered yet, the syntax used to specify dates in queries. WQL does not recognize dates as number items but translates them to its internal format dates specified as text. Many formats are recognized as described in the Microsoft documentation but only one is useful because common to WQL and MariaDB SQL. Here is an example of a query on a table named “cim” created by:

```
CREATE TABLE cim (
  Name VARCHAR(255) NOT NULL,
  LastModified DATETIME NOT NULL)
ENGINE=CONNECT table_type='WMI'
option_list='class=CIM_DataFile,estimate=5000';
```

The date must be specified with the format in which CIM DATETIME values are stored (WMI uses the date and time formats defined by the Distributed Management Task Force).

```
SELECT * FROM cim WHERE drive = 'D:' AND PATH = '\\PlugDB\\Bin\\'
     and lastmodified > '20120415000000.000000+120';
```

This syntax must be strictly respected. The text has the format:

```
yyyymmddHHMMSS.mmmmmmsUUU
```

It is: year, month, day, hour, minute, second, millisecond, and signed minute deviation from UTC. This format is locale-independent so you can write a query that runs on any machine.

Note 1: The WMI table type is available only in Windows versions of CONNECT.

Note 2: WMI tables are read only.

Note 3: WMI tables are not indexable.

Note 4: WMI consider all strings as case insensitive.

MAC Address Table Type “MAC”

Note: This table type is available on Windows only.

This type is used to display various general information about the computer and, in particular, about its network cards. To create such a table, the syntax to use is:

```
CREATE TABLE tabname (COLUMN definition)
ENGINE=CONNECT table_type=MAC;
```

Column names can be freely chosen because their signification, i.e. the values they will display, comes from the specified Flag option. The valid values for Flag are:

Flag	Valeur	Type
1	Host name	varchar(132)
2	Domain	varchar(132)
3	DNS address	varchar(24)
4	Node type	int(1)
5	Scope ID	varchar(256)
6	Routing	int(1)
7	Proxy	int(1)
8	DNS	int(1)
10	Name	varchar(260)
11	Description	varchar(132)
12	MAC address	char(24)
13	Type	int(3)
14	DHCP	int(1)

Flag	Valeur	Type
15	IP address	char(16)
16	SUBNET mask	char(16)
17	GATEWAY	char(16)
18	DHCP server	char(16)
19	Have WINS	int(1)
20	Primary WINS	char(16)
21	Secondary WINS	char(16)
22	Lease obtained	datetime
23	Lease expires	datetime

Note: The information of columns having a Flag value less than 10 are unique for the computer, the other ones are specific to the network cards of the computer.

For instance, you can define the table *macaddr* as:

```
CREATE TABLE MACADDR (
  Host VARCHAR(132) flag=1,
  Card VARCHAR(132) flag=11,
  Address CHAR(24) flag=12,
  IP CHAR(16) flag=15,
  Gateway CHAR(16) flag=17,
  Lease DATETIME flag=23)
ENGINE=CONNECT table_type=MAC;
```

If you execute the query:

```
SELECT host, address, ip, gateway, lease FROM MACADDR;
```

It will return, for example:

Host	Address	IP	Gateway	Lease
OLIVIER	00-A0-D1-A4-61-36	0.0.0.0	0.0.0.0	1970-01-01 00:00:00
OLIVIER	00-1D-E0-9B-90-0B	192.168.0.10	192.168.0.254	2011-09-18 10:28:5

CONNECT Table Types - VIR

VIR Type

A VIR table is a virtual table having only Special or Virtual columns. Its only property is its “size”, or cardinality, meaning the number of virtual rows it contains. It is created using the syntax:

```
CREATE TABLE name [coldef] ENGINE=CONNECT TABLE_TYPE=VIR
[BLOCK_SIZE=n];
```

The optional `BLOCK_SIZE` option gives the size of the table, defaulting to 1 if not specified. When its columns are not specified, it is almost equivalent to a SEQUENCE table “seq_1_to_Size”.

Displaying constants or expressions

Many DBMS use a no-column one-line table to do this, often call “dual”. MySQL and MariaDB use syntax where no table is specified. With CONNECT, you can achieve the same purpose with a virtual table, with the noticeable

advantage of being able to display several lines:

```
CREATE TABLE virt ENGINE=CONNECT table_type=VIR block_size=10;
SELECT concat('The square root of ', n, ' is') what,
round(sqrt(n),16) value FROM virt;
```

This will return:

what	value
The square root of 1 is	1.0000000000000000
The square root of 2 is	1.4142135623730951
The square root of 3 is	1.7320508075688772
The square root of 4 is	2.0000000000000000
The square root of 5 is	2.2360679774997898
The square root of 6 is	2.4494897427831779
The square root of 7 is	2.6457513110645907
The square root of 8 is	2.8284271247461903
The square root of 9 is	3.0000000000000000
The square root of 10 is	3.1622776601683795

What happened here? First of all, unlike Oracle “dual” tableS that have no columns, a MariaDB table must have at least one column. By default, CONNECT creates VIR tables with one special column. This can be seen with the SHOW CREATE TABLE statement:

```
CREATE TABLE `virt` (
`n` INT(11) NOT NULL `SPECIAL`=ROWID,
PRIMARY KEY (`n`)
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='VIR'
`BLOCK_SIZE`=10
```

This special column is called “n” and its value is the row number starting from 1. It is purely a virtual table and no data file exists corresponding to it and to its index.
It is possible to specify the columns of a VIR table but they must be CONNECT special columns or virtual columns. For instance:

```
CREATE TABLE virt2 (
n INT KEY NOT NULL special=ROWID,
sig1 BIGINT AS ((n*(n+1))/2) virtual,
sig2 BIGINT AS(((2*n+1)*(n+1)*n)/6) virtual)
ENGINE=CONNECT table_type=VIR block_size=10000000;
SELECT * FROM virt2 LIMIT 995, 5;
```

This table shows the sum and the sum of the square of the n first integers:

n	sig1	sig2
996	496506	329845486
997	497503	330839495
998	498501	331835499
999	499500	332833500
1000	500500	333833500

Note that the size of the table can be made very big as there no physical data. However, the result should be limited in the queries. For instance:

```
SELECT * FROM virt2 WHERE n = 1664510;
```

Such a query could last very long if the rowid column were not indexed. Note that by default,
CONNECT declares the “n” column as a primary key. Actually, VIR tables can be indexed but only on the ROWID (or ROWNUM) columns of the table. This is a virtual index for which no data is stored.

Generating a Table filled with constant values

An interesting use of virtual tables, which often cannot be achieved with a table of any other type, is to generate a table containing constant values.
This is easily done with a virtual table. Let us define the table FILLER as:

```
CREATE TABLE filler ENGINE=CONNECT table_type=VIR block_size=5000000;
```

Here we choose a size larger than the biggest table we want to generate. Later if we need a table pre- filled with default and/or null values, we can do for example:

```
CREATE TABLE tp (
id INT(6) KEY NOT NULL,
name CHAR(16) NOT NULL,
salary FLOAT(8,2));
INSERT INTO tp SELECT n, 'unknown', NULL FROM filler WHERE n <= 10000;
```

This will generate a table having 10000 rows that can be updated later when needed. Note that a SEQUENCE table could have been used here instead of FILLING .

VIR tables vs. SEQUENCE tables

With just its default column, a VIR table is almost equivalent to a SEQUENCE table. The syntax used is the main difference, for instance:

```
SELECT * FROM seq_100_to_150_step_10;
```

can be obtained with a VIR table (of size >= 15) by:

```
SELECT n*10 FROM vir WHERE n BETWEEN 10 AND 15;
```

Therefore, the main difference is to be able to define the columns of VIR tables. Unfortunately, there are currently many limitations to virtual columns that hopefully should be removed in the future.

CONNECT TBL Table Type: Table List

This type allows defining a table as a list of tables of any engine and type. This is more flexible than multiple tables that must be all of the same file type. This type does, but is more powerful than, what is done with the MERGE engine.

The list of the columns of the TBL table may not necessarily include all the columns of the tables of the list. If the name of some columns is different in the sub-tables, the column to use can be specified by its position given by the `FLAG` option of the column. If the `ACCEPT` option is set to true (Y or 1) columns that do not exist in some of the sub-tables are accepted and their value are null or pseudo-null (this depends on the nullability of the column) for the tables not having this column. The column types can also be different and an automatic conversion are done if necessary.

Note: If not specified, the column definitions are retrieved from the first table of the table list.

The default database of the sub-tables is the current database or if not, can be specified in the DBNAME option. For the tables that are not in the default database, this can be specified in the table list. For instance, to create a table based on the French table *employe* in the current database and on the English table *employee* of the *db2* database, the syntax of the create statement can be:

```
CREATE TABLE allemp (
  SERIALNO char(5) NOT NULL flag=1,
  NAME varchar(12) NOT NULL flag=2,
  SEX smallint(1),
  TITLE varchar(15) NOT NULL flag=3,
  MANAGER char(5) DEFAULT NULL flag=4,
  DEPARTMENT char(4) NOT NULL flag=5,
  SECRETARY char(5) DEFAULT NULL flag=6,
  SALARY double(8,2) NOT NULL flag=7)
ENGINE=CONNECT table_type=TBL
table_list='employe,db2.employee' option_list='Accept=1';
```

The search for columns in sub tables is done by name and, if they exist with a different name, by their position given by a not null `FLAG` option. Column *sex* exists only in the English table (`FLAG` is `0`). Its values will null value for the French table.

For instance, the query:

```
SELECT name, sex, title, salary FROM allemp WHERE department = 318;
```

Can reply:

NAME	SEX	TITLE	SALARY
BARBOUD	NULL	VENDEUR	9700.00
MARCHANT	NULL	VENDEUR	8800.00
MINIARD	NULL	ADMINISTRATIF	7500.00
POUPIN	NULL	INGENIEUR	7450.00
ANTERPE	NULL	INGENIEUR	6850.00
LOULOUTE	NULL	SECRETAIRE	4900.00
TARTINE	NULL	OPERATRICE	2800.00
WERTHER	NULL	DIRECTEUR	14500.00
VOITURIN	NULL	VENDEUR	10130.00
BANCROFT	2	SALESMAN	9600.00
MERCHANT	1	SALESMAN	8700.00
SHRINKY	2	ADMINISTRATOR	7500.00
WALTER	1	ENGINEER	7400.00
TONGHO	1	ENGINEER	6800.00
HONEY	2	SECRETARY	4900.00
PLUMHEAD	2	TYPIST	2800.00
WERTHER	1	DIRECTOR	14500.00
WHEELFOR	1	SALESMAN	10030.00

The first 9 rows, coming from the French table, have a null for the *sex* value. They would have 0 if the sex column had been created NOT NULL.

Subtables of Non-CONNECT Engines

Sub-tables are accessed as PROXY tables. For not CONNECT sub-tables that are accessed via the MySQL API, it is possible like with `PROXY` to change the MYSQL default options. Of course, this will apply to all not CONNECT tables of the list.

Using the TABID Special Column

The TABID special column can be used to see from which table the rows come from and to restrict the access to only some of the sub-tables.

Let us see the following example where t1 and t2 are MyISAM tables similar to the ones given in the `MERGE` description:

```
CREATE TABLE xt1 (
  a INT(11) NOT NULL,
  message CHAR(20))
ENGINE=CONNECT table_type=MYSQL tabname='t1'
option_list='database=test,user=root';

CREATE TABLE xt2 (
  a INT(11) NOT NULL,
  message CHAR(20))
ENGINE=CONNECT table_type=MYSQL tabname='t2'
option_list='database=test,user=root';

CREATE TABLE toto (
  tabname CHAR(8) NOT NULL special='TABID',
  a INT(11) NOT NULL,
  message CHAR(20))
ENGINE=CONNECT table_type=TBL table_list='xt1,xt2';

SELECT * FROM total;
```

The result returned by the `SELECT` statement is:

tabname	a	message
xt1	1	Testing
xt1	2	table
xt1	3	t1
xt2	1	Testing
xt2	2	table
xt2	3	t2

Now if you send the query:

```
SELECT * FROM total WHERE tabname = 'xt2';
```

CONNECT will analyze the where clause and only read the *xt1* table. This can save time if you want to retrieve only a few sub-tables from a TBL table containing many sub-tables.

Parallel Execution

Parallel Execution is currently unavailable until some bugs are fixed.

When the sub-tables are located on different servers, it is possible to execute the remote queries simultaneously instead of sequentially. To enable this, set the thread option to yes.

Additional options available for this table type:

Option	Description
Maxerr	The max number of missing tables in the table list before an error is raised. Defaults to 0.
Accept	If true, missing columns are accepted and return null values. Defaults to false.
Thread	If true, enables parallel execution of remote sub-tables.

These options can be specified in the `OPTION_LIST`.

This page is licensed: GPLv2

CONNECT - Using the TBL and MYSQL Table Types Together

Used together, these types lift all the limitations of the FEDERATED and MERGE engines.

MERGE: Its limitation is obvious, the merged tables must be identical MyISAM tables, and MyISAM is not even the default engine for MariaDB. However, TBL accesses a collection of CONNECT tables, but because these tables can be user specified or internally created MYSQL tables, there is no limitation to the type of the tables that can be merged.

TBL is also much more flexible. The merged tables must not be “identical”, they just should have the columns defined in the TBL table. If the type of one column in a merged table is not the one of the corresponding column of the TBL table, the column value are converted. As we have seen, if one column of the TBL table of the TBL column does not exist in one of the merged table, the corresponding value are set to null. If columns in a sub-table have a different name, they can be accessed by position using the FLAG column option of CONNECT.

However, one limitation of the TBL type regarding MERGE is that TBL tables are currently read-only; INSERT is not supported by TBL. Also, keep using MERGE to access a list of identical MyISAM tables because it are faster, not passing by the MySQL API.

FEDERATED(X): The main limitation of FEDERATED is to access only MySQL/MariaDB tables. The MYSQL table type of CONNECT has the same limitation but CONNECT provides the ODBC table type and JDBC table type that can access tables of any RDBS providing an ODBC or JDBC driver (including MySQL even it is not really useful!)

Another major limitation of FEDERATED is to access only one table. By combining TBL and MYSQL tables, CONNECT enables to access a collection of local or remote tables as one table. Of course the sub-tables can be on different servers. With one SELECT statement, a company manager are able to interrogate results coming from all of his subsidiary computers. This is great for distribution, banking, and many other industries.

Remotely executing complex queries

Many companies or administrations must deal with distributed information. CONNECT enables to deal with it efficiently without having to copy it to a centralized database. Let us suppose we have on some remote network machines_m1, m2, … mn_ some information contained in two tables *t1* and *t2*.

Suppose we want to execute on all servers a query such as:

```
SELECT c1, SUM(c2) FROM t1 a, t2 b WHERE a.id = b.id GROUP BY c1;
```

This raises many problems. Returning the column values of the *t1* and *t2* tables from all servers can be a lot of network traffic. The group by on the possibly huge resulting tables can be a long process. In addition, the join on the *t1* and *t2* tables may be relevant only if the joined tuples belong to the same machine, obliging to add a condition on an additional tabid or servid special column.

All this can be avoided and optimized by forcing the query to be locally executed on each server and retrieving only the small results of the group by queries. Here is how to do it. For each remote machine, create a table that will retrieve the locally executed query. For instance for m1:

```
CREATE TABLE rt1 ENGINE=CONNECT option_list='host=m1'
srcdef='select c1, sum(c2) as sc2 from t1 a, t2 b where a.id = b.id group by c1';
```

Note the alias for the functional column. An alias would be required for the c1 column if its name was different on some machines. The t1 and t2 table names can also be eventually different on the remote machines. The true names must be used in the `SRCDEF` parameter. This will create a set of tables with two columns named c1 and sc2[1].

Then create the table that will retrieve the result of all these tables:

```
CREATE TABLE rtall ENGINE=CONNECT table_type=tbl
table_list='rt1,rt2,…,rtn' option_list='thread=yes';
```

Now you can retrieve the desired result by:

```
SELECT c1, SUM(sc2) FROM rtall;
```

Almost all the work are done on the remote machines, simultaneously thanks to the thread option, making this query super-fast even on big tables placed on many remote machines.

Thread is currently experimental. Use it only for test and report any malfunction on JIRA.

Providing a list of servers

An interesting case is when the query to run on remote machines is the same for all of them. It is then possible to avoid declaring all sub-tables. In this case, the table list option are used to specify the list of servers the `SRCDEF` query must be sent. This is a list of URL's and/or Federated server names.

For instance, supposing that federated servers srv1, srv2, … srv_n_ were created for all remote servers, it are possible to create a tbl table allowing getting the result of a query executed on all of them by:

```
CREATE TABLE qall [column definition]
ENGINE=CONNECT table_type=TBL srcdef='a query'
table_list='srv1,srv2,…,srvn' [option_list='thread=yes'];
```

For instance:

```
CREATE TABLE verall ENGINE=CONNECT table_type=TBL srcdef='select @@version' table_list=',server_one';
SELECT * FROM verall;
```

This reply:

@@**version**
10.0.3-MariaDB-debug
10.0.2-MariaDB

Here the server list specifies a void server corresponding to the local running MariaDB and a federated server named *server_one*.

1. ↑ To generate the columns from the `SRCDEF` query, CONNECT must execute it. This will make sure it is ok. However, if the remote server is not connected yet, or the remote table not existing yet, you can alternatively specify the columns in the create table statement.

This page is licensed: GPLv2

CONNECT VEC Table Type

> **Warning:**
>
> Avoid using this table type in production applications. This file format is specific to CONNECT and may not be supported in future versions.

Tables of type `VEC` are binary files that in some cases can provide good performance on read-intensive query workloads. CONNECT organizes their data on disk as columns of values from the same attribute, as opposed to storing it as rows of tabular records. This organization means that when a query needs to. access only a few columns of a particular table, only those columns need to be read from disk. Conversely, in a row-oriented table, all values in a table are typically read from disk, wasting I/O bandwidth.

CONNECT provides two integral VEC formats, in which each column's data is adjacent.

Integral Vector Formats

In these true vertical formats, the VEC files are made of all the data of the first column, followed by all the data of the second column etc. All this can be in one physical file or each column data can be in a separate file. In the first case, the option max_rows=m, where m is the estimate of the maximum size (number of rows) of the table, must be specified to be able to insert some new records. This leaves an empty space after each column area in which new data can be inserted. In the second case, the "Split" option can be specified[2] at table creation and each column are stored in a file named sequentially from the table file name followed by the rank of the column. Inserting new lines can freely augment such a table.

Differences Between Vector Formats

These formats correspond to different needs. The integral vector format provides the best performance gain. It are chosen when the speed of decisional queries must be optimized.

In the case of a unique file, inserting new data are limited but there will be only one open and close to do. However, the size of the table cannot be calculated from the file size because of the eventual unused space in the file. It must be kept in a header containing the maximum number of rows and the current number of valid rows in the table. To achieve this, specify the option Header=*n* when creating the table. If `n=1` the header are placed at the beginning of the file, if `n=2` it are a separate file with the type '.blk', and if `n=3` the header are place at the end of the file. This last value is provided because batch inserting is sometimes slower when the header is at the beginning of the file. If not specified, the header option will default to 2 for this table type.

On the other hand, the "Split" format with separate files have none of these issues, and is a much safer solution when the table must frequently inserted or shared among several users.

For instance:

```
CREATE TABLE vtab (
a INT NOT NULL,
b CHAR(10) NOT NULL)
ENGINE=CONNECT table_type=VEC file_name='vt.vec';
```

This table, split by default, will have the column values in files vt1.vec and vt2.vec.

For vector tables, the option *block_size=n* is used for block reading and writing; however, to have a file made of blocks of equal size, the internal value of the *max_rows=m* option is eventually increased to become a multiple of n.

Like for BIN tables, numeric values are stored using platform internal layout, the correspondence between column types and internal format being the same than the default ones given above for BIN. However, field formats are not available for VEC tables.

Header Option

This applies to VEC tables that are not split. Because the file size depends on the MAX_ROWS value, CONNECT cannot know how many valid records exist in the file. Depending on the value of the HEADER option, this information is stored in a header that can be placed at the beginning of the file, at the end of the file or in a separate file called fn.blk. The valid values for the HEADER option are:

0	Defaults to 2 for standard tables and to 3 for inward tables.
1	The header is at the beginning of the file.
2	The header is in a separate file.
3	The header is at the end of the file.

The value 2 can be used when dealing with files created by another application with no header. The value 3 makes sometimes inserting in the file faster than when the header is at the beginning of the file.

Note: VEC being a file format specific to CONNECT, no big endian / little endian conversion is provided. These files are not portable between machines using a different byte order setting.

This page is licensed: CC BY-SA / Gnu FDL

CONNECT XCOL Table Type

`XCOL` tables are based on another table or view, like PROXY tables. This type can be used when the object table has a column that contains a list of values.

Suppose we have a *'children'* table that can be displayed as:

name	childlist
Sophie	Vivian, Antony
Lisbeth	Lucy,Charles,Diana
Corinne	
Claude	Marc
Janet	Arthur, Sandra, Peter, John

We can have a different view on these data, where each child are associated with his/her mother by creating an `XCOL` table by:

```
CREATE TABLE xchild (
  mother CHAR(12) NOT NULL,
  child CHAR(12) DEFAULT NULL flag=2
) ENGINE=CONNECT table_type=XCOL tabname='chlist'
option_list='colname=child';
```

The `COLNAME` option specifies the name of the column receiving the list items. This will return from:

```
SELECT * FROM xchild;
```

The requested view:

mother	child
Sophia	Vivian
Sophia	Antony
Lisbeth	Lucy
Lisbeth	Charles

mother	child
Lisbeth	Diana
Corinne	NULL
Claude	Marc
Janet	Arthur
Janet	Sandra
Janet	Peter
Janet	John

Several things should be noted here:

- When the original children field is void, what happens depends on the NULL specification of the “multiple” column. If it is nullable, like here, a void string will generate a NULL value. However, if the column is not nullable, no row are generated at all.
- Blanks after the separator are ignored.
- No copy of the original data was done. Both tables use the same source data.
- Specifying the column definitions in the `CREATE TABLE` statement is optional.

The “multiple” column *child* can be used as any other column. For instance:

```
SELECT * FROM xchild WHERE substr(child,1,1) = 'A';
```

This will return:

Mother	Child
Sophia	Antony
Janet	Arthur

If a query does not involve the “multiple” column, no row multiplication will be done. For instance:

```
SELECT mother FROM xchild;
```

This will just return all the mothers:

mother
Sophia
Lisbeth
Corinne
Claude
Janet

The same occurs with other types of select statements, for instance:

```
SELECT COUNT(*) FROM xchild;      -- returns 5
SELECT COUNT(child) FROM xchild;  -- returns 10
SELECT COUNT(mother) FROM xchild; -- returns 5
```

Grouping also gives different result:

```
SELECT mother, COUNT(*) FROM xchild GROUP BY mother;
```

Replies:

mother	count(*)
Claude	1
Corinne	1
Janet	1
Lisbeth	1
Sophia	1

While the query:

```
SELECT mother, COUNT(child) FROM xchild GROUP BY mother;
```

Gives the more interesting result:

mother	count(child)
Claude	1
Corinne	0
Janet	4
Lisbeth	3
Sophia	2

Some more options are available for this table type:

Option	Description
Sep_char	The separator character used in the “multiple” column, defaults to the comma.
Mult	Indicates the max number of multiple items. It is used to internally calculate the max size of the table and defaults to 10. (To be specified in OPTION_LIST).

Using Special Columns With XCOL

Special columns can be used in XCOL tables. The mostly useful one is ROWNUM that gives the rank of the value in the list of values. For instance:

```
CREATE TABLE xchild2 (
rank INT NOT NULL SPECIAL=ROWID,
mother CHAR(12) NOT NULL,
child CHAR(12) NOT NULL flag=2
) ENGINE=CONNECT table_type=XCOL tabname='chlist' option_list='colname=child';
```

This table are displayed as:

rank	mother	child
1	Sophia	Vivian
2	Sophia	Antony
1	Lisbeth	Lucy
2	Lisbeth	Charles
3	Lisbeth	Diana
1	Claude	Marc
1	Janet	Arthur

rank	mother	child
2	Janet	Sandra
3	Janet	Peter
4	Janet	John

To list only the first child of each mother you can do:

```
SELECT mother, child FROM xchild2 WHERE rank = 1 ;
```

returning:

mother	child
Sophia	Vivian
Lisbeth	Lucy
Claude	Marc
Janet	Arthur

However, note the following pitfall: trying to get the names of all mothers having more than 2 children cannot be done by:

```
SELECT mother FROM xchild2 WHERE rank > 2;
```

This is because with no row multiplication being done, the rank value is always 1. The correct way to obtain this result is longer but cannot use the ROWNUM column:

```
SELECT mother FROM xchild2 GROUP BY mother HAVING COUNT(child) > 2;
```

XCOL Tables Based on Specified Views

Instead of specifying a source table name via the `TABNAME` option, it is possible to retrieve data from a "view" whose definition is given in a new option `SRCDEF` . For instance:

```
CREATE TABLE xsvars ENGINE=CONNECT table_type=XCOL
srcdef='show variables like "optimizer_switch"'
option_list='Colname=Value';
```

Then, for instance:

```
SELECT value FROM xsvars LIMIT 10;
```

This will display something like:

value
index_merge=on
index_merge_union=on
index_merge_sort_union=on
index_merge_intersection=on
index_merge_sort_intersection=off
engine_condition_pushdown=off
index_condition_pushdown=on
derived_merge=on

value
derived_with_keys=on
firstmatch=on

Note: All XCOL tables are read only.

This page is licensed: CC BY-SA / Gnu FDL

CONNECT XML Table Type

Overview

CONNECT supports tables represented by XML files. For these tables, the standard input/output functions of the operating system are not used but the parsing and processing of the file is delegated to a specialized library. Currently two such systems are supported: libxml2, a part of the GNOME framework, but which does not require GNOME and, on Windows, MS-DOM (DOMDOC), the Microsoft standard support of XML documents.

DOMDOC is the default for the Windows version of CONNECT and libxml2 is always used on other systems. On Windows the choice can be specified using the XMLSUP CREATE TABLE list option, for instance specifying `option_list='xmlsup=libxml2'`.

Creating XML Tables

First of all, it must be understood that XML is a very general language used to encode data having any structure. In particular, the tag hierarchy in an XML file describes a tree structure of the data. For instance, consider the file:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<BIBLIO SUBJECT="XML">
   <BOOK ISBN="9782212090819" LANG="fr" SUBJECT="applications">
      <AUTHOR>
         <FIRSTNAME>Jean-Christophe</FIRSTNAME>
         <LASTNAME>Bernadac</LASTNAME>
      </AUTHOR>
      <AUTHOR>
         <FIRSTNAME>François</FIRSTNAME>
         <LASTNAME>Knab</LASTNAME>
      </AUTHOR>
      <TITLE>Construire une application XML</TITLE>
      <PUBLISHER>
         <NAME>Eyrolles</NAME>
         <PLACE>Paris</PLACE>
      </PUBLISHER>
      <DATEPUB>1999</DATEPUB>
   </BOOK>
   <BOOK ISBN="9782840825685" LANG="fr" SUBJECT="applications">
      <AUTHOR>
         <FIRSTNAME>William J.</FIRSTNAME>
         <LASTNAME>Pardi</LASTNAME>
      </AUTHOR>
      <TRANSLATOR PREFIX="adapté de l'anglais par">
         <FIRSTNAME>James</FIRSTNAME>
         <LASTNAME>Guerin</LASTNAME>
      </TRANSLATOR>
      <TITLE>XML en Action</TITLE>
      <PUBLISHER>
         <NAME>Microsoft Press</NAME>
         <PLACE>Paris</PLACE>
      </PUBLISHER>
      <DATEPUB>1999</DATEPUB>
   </BOOK>
</BIBLIO>
```

It represents data having the structure:

```
<BIBLIO>
                          ___________|_________
                         |                     |
            <BOOK:ISBN,LANG,SUBJECT>           |
          _________________|_________________    |
         |        |         |           |     |
     <AUTHOR> <TITLE> <PUBLISHER> <DATEPUB> |
    ____|____            ___|____          |
   |    |    |          |        |          |
<FIRST> | <LAST>     <NAME>   <PLACE>       |
        |                                    |
     <AUTHOR>                  <BOOK:ISBN,LANG,SUBJECT>
    ____|____          _____________________|_________________
   |         |       |             |         |        |         |
<FIRST>   <LAST>  <AUTHOR> <TRANSLATOR> <TITLE> <PUBLISHER> <DATEPUB>
               _____|_        ___|___           ___|____
              |       |      |       |         |        |
            <FIRST> <LAST> <FIRST> <LAST>     <NAME>   <PLACE>
```

This structure seems at first view far from being tabular. However, modern database management systems, including MariaDB, implement something close to the relational model and work on tables that are structurally not hierarchical but tabular with rows and columns.

Nevertheless, CONNECT can do it. Of course, it cannot guess what you want to extract from the XML structure, but gives you the possibility to specify it when you create the table[1].

Let us take a first example. Suppose you want to make a table from the above document, displaying the node contents.

For this, you can define a table *xsamptag* as:

```
CREATE TABLE xsamptag (
  AUTHOR CHAR(50),
  TITLE CHAR(32),
  TRANSLATOR CHAR(40),
  PUBLISHER CHAR(40),
  DATEPUB INT(4))
ENGINE=CONNECT table_type=XML file_name='Xsample.xml';
```

It are displayed as:

AUTHOR	TITLE	TRANSLATOR	PUBLISHER	DATEPUB
Jean-Christophe Bernadac	Construire une application XML		Eyrolles Paris	1999
William J. Pardi	XML en Action	James Guerin	Microsoft Press Paris	1999

Let us try to understand what happened. By default the column names correspond to tag names. Because this file is rather simple, CONNECT was able to default the top tag of the table as the root node `<BIBLIO>` of the file, and the row tags as the `<BOOK>` children of the table tag. In a more complex file, this should have been specified, as we will see later. Note that we didn't have to worry about the sub-tags such as `<FIRSTNAME>` or `<LASTNAME>` because CONNECT automatically retrieves the entire text contained in a tag and its sub-tags[2].

Only the first author of the first book appears. This is because only the first occurrence of a column tag has been retrieved so the result has a proper tabular structure. We will see later what we can do about that.

How can we retrieve the values specified by attributes? By using a *Coltype* table option to specify the default column type. The value '@' means that column names match attribute names. Therefore, we can retrieve them by creating a table such as:

```
CREATE TABLE xsampattr (
  ISBN CHAR(15),
  LANG CHAR(2),
  SUBJECT CHAR(32))
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
option_list='Coltype=@';
```

This table returns the following:

ISBN	LANG	SUBJECT
9782212090819	fr	applications
9782840825685	fr	applications

Now to define a table that will give us all the previous information, we must specify the column type for each column. Because in the next statement the column type defaults to Node, the *field_format* column parameter was used to indicate which columns are attributes:

From Connect 1.7.0002

```
CREATE TABLE xsamp (
ISBN CHAR(15) xpath='@',
LANG CHAR(2) xpath='@',
SUBJECT CHAR(32) xpath='@',
AUTHOR CHAR(50),
TITLE CHAR(32),
TRANSLATOR CHAR(40),
PUBLISHER CHAR(40),
DATEPUB INT(4))
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK';
```

Before Connect 1.7.0002

```
CREATE TABLE xsamp (
  ISBN CHAR(15) field_format='@',
  LANG CHAR(2) field_format='@',
  SUBJECT CHAR(32) field_format='@',
  AUTHOR CHAR(50),
  TITLE CHAR(32),
  TRANSLATOR CHAR(40),
  PUBLISHER CHAR(40),
  DATEPUB INT(4))
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK';
```

Once done, we can enter the query:

```
SELECT subject, lang, title, author FROM xsamp;
```

This will return the following result:

SUBJECT	LANG	TITLE	AUTHOR
applications	fr	Construire une application XML	Jean-Christophe Bernadac
applications	fr	XML en Action	William J. Pardi

Note that we have been lucky. Because unlike SQL, XML is case sensitive and the column names have matched the node names only because the column names were given in upper case. Note also that the order of the columns in the table could have been different from the order in which the nodes appear in the XML file.

Using Xpaths With XML Tables

Xpath is used by XML to locate and retrieve nodes. The table's main node Xpath is specified by the `tabname` option. If just the node name is given, CONNECT constructs an Xpath such as `'BIBLIO'` in the example above that should retrieve the `BIBLIO` node wherever it is within the XML file.

The row nodes are by default the children of the table node. However, for instance to eliminate some children nodes that are not real row nodes, the row node name can be specified using the `rownode` sub-option of the `option_list` option.

The field_format options we used above can be specified to locate more precisely where and what information to retrieve using an Xpath-like syntax. For instance:

From Connect 1.7.0002

```
CREATE TABLE xsampall (
isbn CHAR(15) xpath='@ISBN',
LANGUAGE CHAR(2) xpath='@LANG',
subject CHAR(32) xpath='@SUBJECT',
authorfn CHAR(20) xpath='AUTHOR/FIRSTNAME',
authorln CHAR(20) xpath='AUTHOR/LASTNAME',
title CHAR(32) xpath='TITLE',
translated CHAR(32) xpath='TRANSLATOR/@PREFIX',
tranfn CHAR(20) xpath='TRANSLATOR/FIRSTNAME',
tranln CHAR(20) xpath='TRANSLATOR/LASTNAME',
publisher CHAR(20) xpath='PUBLISHER/NAME',
LOCATION CHAR(20) xpath='PUBLISHER/PLACE',
YEAR INT(4) xpath='DATEPUB')
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK';
```

Before Connect 1.7.0002

```
CREATE TABLE xsampall (
  isbn CHAR(15) field_format='@ISBN',
  LANGUAGE CHAR(2) field_format='@LANG',
  subject CHAR(32) field_format='@SUBJECT',
  authorfn CHAR(20) field_format='AUTHOR/FIRSTNAME',
  authorln CHAR(20) field_format='AUTHOR/LASTNAME',
  title CHAR(32) field_format='TITLE',
  translated CHAR(32) field_format='TRANSLATOR/@PREFIX',
  tranfn CHAR(20) field_format='TRANSLATOR/FIRSTNAME',
  tranln CHAR(20) field_format='TRANSLATOR/LASTNAME',
  publisher CHAR(20) field_format='PUBLISHER/NAME',
  LOCATION CHAR(20) field_format='PUBLISHER/PLACE',
  YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK';
```

This very flexible column parameter serves several purposes:

- To specify the tag name, or the attribute name if different from the column name.
- To specify the type (tag or attribute) by a prefix of '@' for attributes.
- To specify the path for sub-tags using the '/' character.

This path is always relative to the current context (the column top node) and cannot be specified as an absolute path from the document root, therefore a leading '/' cannot be used. The path cannot be variable in node names or depth, therefore using '`//`' is not allowed.

The query:

```
SELECT isbn, title, translated, tranfn, tranln, LOCATION FROM
    xsampall WHERE translated IS NOT NULL;
```

replies:

ISBN	TITLE	TRANSLATED	TRANFN	TRANLN	LOCATION
9782840825685	XML en Action	adapté de l'anglais par	James	Guerin	Paris

Libxml2 Default Name Space Issue

An issue with libxml2 is that some files can declare a default name space in their root node. Because Xpath only searches in that name space, the nodes will not be found if they are not prefixed. If this happens, specify the tabname option as an Xpath ignoring the current name space:

```
TABNAME="//*[local-name()='BIBLIO']"
```

This must also be done for the default of specified Xpath of the not attribute columns. For instance:

```
title char(32) field_format="*[local-name()='TITLE']",
```

Note: This raises an error (and is useless anyway) with DOMDOC.

Direct Access on XML Tables

Direct access is available on XML tables. This means that XML tables can be sorted and used in joins, even in the one-side of the join.

However, building a permanent index is not yet implemented. It is unclear whether this can be useful. Indeed, the DOM implementation that is used to access these tables firstly parses the whole file and constructs a node tree in memory. This may often be the longest part of the process, so the use of an index would not be of great value. Note also that this limits the XML files to a reasonable size. Anyway, when speed is important, this table type is not the best to use. Therefore, in these cases, it is probably better to convert the file to another type by inserting the XML table into another table of a more appropriate type for performance.

Accessing Tags With Namespaces

With the Windows DOMDOC support, this can be done using the prefix in the tabname column option and/or xpath column option. For instance, given the file gns.xml:

```
<?xml version="1.0" encoding="UTF-8"?>
<gpx xmlns:gns="http:dummy">
<gns:trkseg>
<trkpt lon="-121.9822235107421875" lat="37.3884925842285156">
<gns:ele>6.610851287841797</gns:ele>
<time>2014-04-01T14:54:05.000Z</time>
</trkpt>
<trkpt lon="-121.9821929931640625" lat="37.3885803222656250">
<ele>6.787827968597412</ele>
<time>2014-04-01T14:54:08.000Z</time>
</trkpt>
<trkpt lon="-121.9821624755859375" lat="37.3886299133300781">
<ele>6.771987438201904</ele>
<time>2014-04-01T14:54:10.000Z</time>
</trkpt>
</gns:trkseg>
</gpx>
```

and the defined CONNECT table:

```
CREATE TABLE xgns (
`lon` DOUBLE(21,16) NOT NULL `xpath`='@',
`lat` DOUBLE(20,16) NOT NULL `xpath`='@',
`ele` DOUBLE(21,16) NOT NULL `xpath`='gns:ele',
`time` DATETIME date_format="YYYY-MM-DD 'T' hh:mm:ss '.000Z'"
)
  ENGINE=CONNECT DEFAULT CHARSET=latin1 `table_type`=XML
  `file_name`='gns.xml' tabname='gns:trkseg' option_list='xmlsup=domdoc';
```

```
SELECT * FROM xgns;
```

Displays:

lon	lat	ele	time
-121,982223510742	37,3884925842285	6,6108512878418	01/04/2014 14:54:05
-121,982192993164	37,3885803222656	0	01/04/2014 14:54:08
-121,982162475586	37,3886299133301	0	01/04/2014 14:54:10

Only the prefixed 'ele' tag is recognized.

However, this does not work with the libxml2 support. The solution is then to use a function ignoring the name space:

```
CREATE TABLE xgns2 (
`lon` DOUBLE(21,16) NOT NULL `xpath`='@',
`lat` DOUBLE(20,16) NOT NULL `xpath`='@',
`ele` DOUBLE(21,16) NOT NULL `xpath`="*[local-name()='ele']",
`time` DATETIME date_format="YYYY-MM-DD 'T' hh:mm:ss '.000Z'"
)
  ENGINE=CONNECT DEFAULT CHARSET=latin1 `table_type`=XML
  `file_name`='gns.xml' tabname="*[local-name()='trkseg']" option_list='xmlsup=libxml2';
```

Then :

```
SELECT * FROM xgns2;
```

Displays:

lon	lat	ele	time
-121,982223510742	37,3884925842285	6,6108512878418	01/04/2014 14:54:05
-121,982192993164	37,3885803222656	6.7878279685974	01/04/2014 14:54:08
-121,982162475586	37,3886299133301	6.7719874382019	01/04/2014 14:54:10

This time, all 'ele` tags are recognized. This solution does not work with DOMDOC.

Having Columns Defined by Discovery

It is possible to let the MariaDB discovery process do the job of column specification. When columns are not defined in the CREATE TABLE statement, CONNECT endeavours to analyze the XML file and to provide the column specifications. This is possible only for true XML tables, but not for HTML tables.

For instance, the *xsamp* table could have been created specifying:

```
CREATE TABLE xsamp
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK';
```

Let's check how it was actually specified using the SHOW CREATE TABLE statement:

```
CREATE TABLE `xsamp` (
  `ISBN` CHAR(13) NOT NULL `FIELD_FORMAT`='@',
  `LANG` CHAR(2) NOT NULL `FIELD_FORMAT`='@',
  `SUBJECT` CHAR(12) NOT NULL `FIELD_FORMAT`='@',
  `AUTHOR` CHAR(24) NOT NULL,
  `TRANSLATOR` CHAR(12) DEFAULT NULL,
  `TITLE` CHAR(30) NOT NULL,
  `PUBLISHER` CHAR(21) NOT NULL,
  `DATEPUB` CHAR(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='XML'
  `FILE_NAME`='E:/Data/Xml/Xsample.xml' `TABNAME`='BIBLIO' `OPTION_LIST`='rownode=BOOK';
```

It is equivalent except for the column sizes that have been calculated from the file as the maximum length of the corresponding column when it was a normal value. Also, all columns are specified as type CHAR because XML does not provide information about the node content data type. Nullable is set to true if the column is missing in some rows.

If a more complex definition is desired, you can ask CONNECT to analyse the XPATH up to a given level using the level option in the option list. The level value is the number of nodes that are taken in the XPATH. For instance:

```
CREATE TABLE xsampall
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK,Level=1';
```

This will define the table as:

From Connect 1.7.0002

```
CREATE TABLE `xsampall` (
  `ISBN` CHAR(13) NOT NULL `XPATH`='@',
  `LANG` CHAR(2) NOT NULL `XPATH`='@',
  `SUBJECT` CHAR(12) NOT NULL `XPATH`='@',
  `AUTHOR_FIRSTNAME` CHAR(15) NOT NULL `XPATH`='AUTHOR/FIRSTNAME',
  `AUTHOR_LASTNAME` CHAR(8) NOT NULL `XPATH`='AUTHOR/LASTNAME',
  `TRANSLATOR_PREFIX` CHAR(24) DEFAULT NULL `XPATH`='TRANSLATOR/@PREFIX',
  `TRANSLATOR_FIRSTNAME` CHAR(7) DEFAULT NULL `XPATH`='TRANSLATOR/FIRSTNAME',
  `TRANSLATOR_LASTNAME` CHAR(6) DEFAULT NULL `XPATH`='TRANSLATOR/LASTNAME',
  `TITLE` CHAR(30) NOT NULL,
  `PUBLISHER_NAME` CHAR(15) NOT NULL `XPATH`='PUBLISHER/NAME',
  `PUBLISHER_PLACE` CHAR(5) NOT NULL `XPATH`='PUBLISHER/PLACE',
  `DATEPUB` CHAR(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='XML' `FILE_NAME`='Xsample.xml' `TABNAME`='BIBLIO'
`OPTION_LIST`='rownode=BOOK,Depth=1';
<</SQL>>

BEFORE CONNECT 1.7.0002
<<SQL>>
CREATE TABLE `xsampall` (
  `ISBN` CHAR(13) NOT NULL `FIELD_FORMAT`='@',
  `LANG` CHAR(2) NOT NULL `FIELD_FORMAT`='@',
  `SUBJECT` CHAR(12) NOT NULL `FIELD_FORMAT`='@',
  `AUTHOR_FIRSTNAME` CHAR(15) NOT NULL `FIELD_FORMAT`='AUTHOR/FIRSTNAME',
  `AUTHOR_LASTNAME` CHAR(8) NOT NULL `FIELD_FORMAT`='AUTHOR/LASTNAME',
  `TRANSLATOR_PREFIX` CHAR(24) DEFAULT NULL `FIELD_FORMAT`='TRANSLATOR/@PREFIX',
  `TRANSLATOR_FIRSTNAME` CHAR(7) DEFAULT NULL `FIELD_FORMAT`='TRANSLATOR/FIRSTNAME',
  `TRANSLATOR_LASTNAME` CHAR(6) DEFAULT NULL `FIELD_FORMAT`='TRANSLATOR/LASTNAME',
  `TITLE` CHAR(30) NOT NULL,
  `PUBLISHER_NAME` CHAR(15) NOT NULL `FIELD_FORMAT`='PUBLISHER/NAME',
  `PUBLISHER_PLACE` CHAR(5) NOT NULL `FIELD_FORMAT`='PUBLISHER/PLACE',
  `DATEPUB` CHAR(4) NOT NULL
) ENGINE=CONNECT DEFAULT CHARSET=latin1 `TABLE_TYPE`='XML' `FILE_NAME`='Xsample.xml'
  `TABNAME`='BIBLIO' `OPTION_LIST`='rownode=BOOK,Level=1';
<</SQL>>

This METHOD can be used AS a quick way TO make a “TEMPLATE” TABLE definition that can later be edited TO
make the desired definition. IN particular, COLUMN NAMES ARE constructed FROM ALL the nodes OF their PATH
IN ORDER TO have DISTINCT COLUMN names. This can be manually edited TO have the desired NAMES, provided
their XPATH IS NOT modified.

TO have a preview OF how columns are DEFINED, you can USE a CATALOG TABLE like this:

<<SQL>>
CREATE TABLE xsacol
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK,Level=1' catfunc=col;
<</SQL>>

AND WHEN asking:

<<SQL>>
SELECT COLUMN_NAME Name, type_name TYPE, column_size SIZE, NULLABLE, xpath FROM xsacol;
<</SQL>>

You GET the description OF what the TABLE columns are:

<<style CLASS="darkheader-nospace-borders">>
|= Name |= TYPE |= SIZE |= NULLABLE |= xpath |
| ISBN | CHAR | 13 | 0 | @ |
| LANG | CHAR | 2 | 0 | @ |
| SUBJECT | CHAR | 12 | 0 | @ |
| AUTHOR_FIRSTNAME | CHAR | 15 | 0 | AUTHOR/FIRSTNAME |
| AUTHOR_LASTNAME | CHAR | 8 | 0 | AUTHOR/LASTNAME |
| TRANSLATOR_PREFIX | CHAR | 24 | 1 | TRANSLATOR/@PREFIX |
| TRANSLATOR_FIRSTNAME | CHAR | 7 | 1 | TRANSLATOR/FIRSTNAME |
| TRANSLATOR_LASTNAME | CHAR | 6 | 1 | TRANSLATOR/LASTNAME |
| TITLE | CHAR | 30 | 0 |  |
```

```
| PUBLISHER_NAME | CHAR | 15 | 0 | PUBLISHER/NAME |
| PUBLISHER_PLACE | CHAR | 5 | 0 | PUBLISHER/PLACE |
| DATEPUB | CHAR | 4 | 0 | |
<</style>>

== WRITE operations ON XML TABLES
You can freely USE the UPDATE, DELETE AND INSERT commands WITH XML tables.
However, you must understand that the format OF the updated OR inserted DATA
follows the specifications OF the TABLE you created, NOT the ones OF the
original SOURCE file. FOR INSTANCE, let us suppose we INSERT a NEW book USING
the //xsamp// TABLE (NOT the //xsampall// TABLE) WITH the command:

<<code lang=mysql INLINE=FALSE>>
INSERT INTO xsamp
  (isbn, lang, subject, author, title, publisher,datepub)
  VALUES ('9782212090529','fr','général','Alain Michard',
         'XML, Language et Applications','Eyrolles Paris',1998);
```

Then if we ask:

```
SELECT subject, author, title, translator, publisher FROM xsamp;
```

Everything seems correct when we get the result:

SUBJECT	AUTHOR	TITLE	TRANSLATOR	PUBLISHER
applications	Jean-Christophe Bernadac	Construire une application XML		Eyrolles Paris
applications	William J. Pardi	XML en Action	James Guerin	Microsoft Press Paris
général	Alain Michard	XML, Language et Applications		Eyrolles Paris

However if we enter the apparently equivalent query on the *xsampall* table, based on the same file:

```
SELECT subject,
concat(authorfn, ' ', authorln) author , title,
concat(tranfn, ' ', tranln) translator,
concat(publisher, ' ', LOCATION) publisher FROM xsampall;
```

this returns an apparently wrong answer:

SUBJECT	AUTHOR	TITLE	TRANSLATOR	PUBLISHER
applications	Jean-Christophe Bernadac	Construire une application XML		Eyrolles Paris
applications	William J. Pardi	XML en Action	James Guerin	Microsoft Press Paris
général		XML, Language et Applications		

What happened here? Simply, because we used the *xsamp* table to do the Insert, what has been inserted within the XML file had the structure described for *xsamp*:

```
<BOOK ISBN="9782212090529" LANG="fr" SUBJECT="général">
      <AUTHOR>Alain Michard</AUTHOR>
      <TITLE>XML, Language et Applications</TITLE>
      <TRANSLATOR></TRANSLATOR>
      <PUBLISHER>Eyrolles Paris</PUBLISHER>
      <DATEPUB>1998</DATEPUB>
   </BOOK>
```

CONNECT cannot “invent” sub-tags that are not part of the *xsamp* table. Because these sub-tags do not exist, the *xsampall* table cannot retrieve the information that should be attached to them. If we want to be able to query the XML file by all the defined tables, the correct way to insert a new book to the file is to use the *xsampall* table, the only one that addresses all the components of the original document:

```
DELETE FROM xsamp WHERE isbn = '9782212090529';

INSERT INTO xsampall (isbn, LANGUAGE, subject, authorfn, authorln,
      title, publisher, LOCATION, YEAR)
   VALUES('9782212090529','fr','général','Alain','Michard',
      'XML, Language et Applications','Eyrolles','Paris',1998);
```

Now the added book, in the XML file, will have the required structure:

```
<BOOK ISBN="9782212090529" LANG="fr" SUBJECT="général">
      <AUTHOR>
         <FIRSTNAME>Alain</FIRSTNAME>
         <LASTNAME>Michard</LASTNAME>
      </AUTHOR>
      <TITLE>XML, Language et Applications</TITLE>
      <PUBLISHER>
         <NAME>Eyrolles</NAME>
         <PLACE>Paris</PLACE>
      </PUBLISHER>
      <DATEPUB>1998</DATEPUB>
   </BOOK>
```

Note: We used a column list in the Insert statements when creating the table to avoid generating a `<TRANSLATOR>` node with sub-nodes, all containing null values (this works on Windows only).

Multiple Nodes in the XML Document

Let us come back to the above example XML file. We have seen that the author node can be “multiple” meaning that there can be more than one author of a book. What can we do to get the complete information fitting the relational model? CONNECT provides you with two possibilities, but is restricted to only one such multiple node per table.

The first and most challenging one is to return as many rows than there are authors, the other columns being repeated as if we had make a join between the author column and the rest of the table. To achieve this, simply specify the
“multiple” node name and the “expand” option when creating the table. For instance, we can create the *xsamp2* table like this:

```
CREATE TABLE xsamp2 (
  ISBN CHAR(15) field_format='@',
  LANG CHAR(2) field_format='@',
  SUBJECT CHAR(32) field_format='@',
  AUTHOR CHAR(40),
  TITLE CHAR(32),
  TRANSLATOR CHAR(32),
  PUBLISHER CHAR(32),
  DATEPUB INT(4))
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO'
option_list='rownode=BOOK,Expand=1,Mulnode=AUTHOR,Limit=2';
```

In this statement, the Limit option specifies the maximum number of values that are expanded. If not specified, it defaults to `10`. Any values above the limit are ignored and a warning message issued[3]. Now you can enter a query such as:

```
SELECT isbn, subject, author, title FROM xsamp2;
```

This will retrieve and display the following result:

ISBN	SUBJECT	AUTHOR	TITLE
9782212090819	applications	Jean-Christophe Bernadac	Construire une application XML

ISBN	SUBJECT	AUTHOR	TITLE
9782212090819	applications	François Knab	Construire une application XML
9782840825685	applications	William J. Pardi	XML en Action
9782212090529	général	Alain Michard	XML, Language et Applications

In this case, this is as if the table had four rows. However if we enter the query:

```
SELECT isbn, subject, title, publisher FROM xsamp2;
```

this time the result are:

ISBN	SUBJECT	TITLE	PUBLISHER
9782212090819	applications	Construire une application XML	Eyrolles Paris
9782840825685	applications	XML en Action	Microsoft Press Paris
9782212090529	général	XML, Language et Applications	Eyrolles Paris

Because the author column does not appear in the query, the corresponding row was not expanded. This is somewhat strange because this would have been different if we had been working on a table of a different type. However, it is closer to the relational model for which there should not be two identical rows (tuples) in a table. Nevertheless, you should be aware of this somewhat erratic behavior. For instance:

```
SELECT COUNT(*) FROM xsamp2;               /* Replies 3 */
SELECT COUNT(author) FROM xsamp2;          /* Replies 4 */
SELECT COUNT(isbn) FROM xsamp2;            /* Replies 3 */
SELECT isbn, subject, title, publisher FROM xsamp2 WHERE author <> '';
```

This last query replies:

ISBN	SUBJECT	TITLE	PUBLISHER
9782212090819	applications	Construire une application XML	Eyrolles Paris
9782212090819	applications	Construire une application XML	Eyrolles Paris
9782840825685	applications	XML en Action	Microsoft Press Paris
9782212090529	général	XML, Language et Applications	Eyrolles Paris

Even though the author column does not appear in the result, the corresponding row was expanded because the multiple column was used in the where clause.

Intermediate Multiple Node

The “multiple” node can be an intermediate node. If we want to do the same expanding with the *xsampall* table, there are nothing more to do. The_xsampall2_ table can be created with:

From Connect 1.7.0002

```
CREATE TABLE xsampall2 (
isbn CHAR(15) xpath='@ISBN',
LANGUAGE CHAR(2) xpath='@LANG',
subject CHAR(32) xpath='@SUBJECT',
authorfn CHAR(20) xpath='AUTHOR/FIRSTNAME',
authorln CHAR(20) xpath='AUTHOR/LASTNAME',
title CHAR(32) xpath='TITLE',
translated CHAR(32) xpath='TRANSLATOR/@PREFIX',
tranfn CHAR(20) xpath='TRANSLATOR/FIRSTNAME',
tranln CHAR(20) xpath='TRANSLATOR/LASTNAME',
publisher CHAR(20) xpath='PUBLISHER/NAME',
LOCATION CHAR(20) xpath='PUBLISHER/PLACE',
YEAR INT(4) xpath='DATEPUB')
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO' option_list='rownode=BOOK,Expand=1,Mulnode=AUTHOR,Limit=2';
```

Before Connect 1.7.0002

```
CREATE TABLE xsampall2 (
  isbn CHAR(15) field_format='@ISBN',
  LANGUAGE CHAR(2) field_format='@LANG',
  subject CHAR(32) field_format='@SUBJECT',
  authorfn CHAR(20) field_format='AUTHOR/FIRSTNAME',
  authorln CHAR(20) field_format='AUTHOR/LASTNAME',
  title CHAR(32) field_format='TITLE',
  translated CHAR(32) field_format='TRANSLATOR/@PREFIX',
  tranfn CHAR(20) field_format='TRANSLATOR/FIRSTNAME',
  tranln CHAR(20) field_format='TRANSLATOR/LASTNAME',
  publisher CHAR(20) field_format='PUBLISHER/NAME',
  LOCATION CHAR(20) field_format='PUBLISHER/PLACE',
  YEAR INT(4) field_format='DATEPUB')
ENGINE=CONNECT table_type=XML file_name='Xsample.xml'
tabname='BIBLIO'
option_list='rownode=BOOK,Expand=1,Mulnode=AUTHOR,Limit=2';
```

The only difference is that the “multiple” node is an intermediate node in the path. The resulting table can be seen with a query such as:

```
SELECT subject, LANGUAGE lang, title, authorfn FIRST, authorln
    LAST, YEAR FROM xsampall2;
```

This query displays:

SUBJECT	LANG	TITLE	FIRST	LAST	YEAR
applications	fr	Construire une application XML	Jean-Christophe	Bernadac	1999
applications	fr	Construire une application XML	François	Knab	1999
applications	fr	XML en Action	William J.	Pardi	1999
général	fr	XML, Language et Applications	Alain	Michard	1998

These composite tables, half array half tree, reserve some surprises for us when updating, deleting from or inserting into them. Insert just cannot generate this structure; if two rows are inserted with just a different author, two book nodes are generated in the XML file. Delete always deletes one book node and all its children nodes even if specified against only one author. Update is more complicated:

```
UPDATE xsampall2 SET authorfn = 'Simon' WHERE authorln = 'Knab';
UPDATE xsampall2 SET YEAR = 2002 WHERE authorln = 'Bernadac';
UPDATE xsampall2 SET authorln = 'Mercier' WHERE YEAR = 2002;
```

After these three updates, the first two responding “Affected rows: 1” and the last one responding “Affected rows: 2”, the last query answers:

subject	lang	title	first	last	year
applications	fr	Construire une application XML	Jean-Christophe	Mercier	2002
applications	fr	Construire une application XML	François	Knab	2002
applications	fr	XML en Action	William J.	Pardi	1999
général	fr	XML, Language et Applications	Alain	Michard	1998

What must be understood here is that the Update modifies node values in the XML file, not cell values in the relational table. The first update worked normally. The second update changed the year value of the book and this shows for the two expanded rows because there is only one DATEPUB node for that book. Because the third update applies to a row having a certain date value, both author names were updated.

Making a List of Multiple Values

Another way to see multiple values is to ask CONNECT to make a comma separated list of the multiple node values. This time, it can only be done if the “multiple” node is not intermediate. For example, we can modify the *xsamp2* table definition by:

```
ALTER TABLE xsamp2 option_list='rownode=BOOK,Mulnode=AUTHOR,Limit=3';
```

This time ‘Expand’ is not specified, and Limit gives the maximum number of items in the list. Now if we enter the query:

```
SELECT isbn, subject, author "AUTHOR(S)", title FROM xsamp2;
```

We will get the following result:

ISBN	SUBJECT	AUTHOR(S)	TITLE
9782212090819	applications	Jean-Christophe Bernadac, François Knab	Construire une application XML
9782840825685	applications	William J. Pardi	XML en Action
9782212090529	général	Alain Michard	XML, Language et Applications

Note that updating the “multiple” column is not possible because CONNECT does not know which of the nodes to update.

This could not have been done with the *xsampall2* table because the author node is intermediate in the path, and making two lists, one of first names and another one of last names would not make sense anyway.

What if a table contains several multiple nodes

This can be handled by creating several tables on the same file, each containing only one multiple node and constructing the desired result using joins.

Support of HTML Tables

Most tables included in HTML documents cannot be processed by CONNECT because the HTML language is often not compatible with the syntax of XML. In particular, XML requires all open tags to be matched by a closing tag while it is sometimes optional in HTML. This is often the case concerning column tags.

However, you can meet tables that respect the XML syntax but have some of the features of HTML tables. For instance:

```
<?xml version="1.0"?>
<Beers>
  <table>
    <th><td>Name</td><td>Origin</td><td>Description</td></th>
    <tr>
      <td><brandName>Huntsman</brandName></td>
      <td><origin>Bath, UK</origin></td>
      <td><details>Wonderful hop, light alcohol</details></td>
    </tr>
    <tr>
      <td><brandName>Tuborg</brandName></td>
      <td><origin>Danmark</origin></td>
      <td><details>In small bottles</details></td>
    </tr>
  </table>
</Beers>
```

Here the different column tags are included in `<td></td>` tags as for HTML tables. You cannot just add this tag in the Xpath of the columns, because the search is done on the first occurrence of each tag, and this would cause this search to fail for all columns except the first one. This case is handled by specifying the *Colnode* table option that gives the name of these column tags, for example:

From Connect 1.7.0002

```
CREATE TABLE beers (
`Name` CHAR(16) xpath='brandName',
`Origin` CHAR(16) xpath='origin',
`Description` CHAR(32) xpath='details')
ENGINE=CONNECT table_type=XML file_name='beers.xml'
tabname='table' option_list='rownode=tr,colnode=td';
```

Before Connect 1.7.0002

```
CREATE TABLE beers (
  `Name` CHAR(16) field_format='brandName',
  `Origin` CHAR(16) field_format='origin',
  `Description` CHAR(32) field_format='details')
ENGINE=CONNECT table_type=XML file_name='beers.xml'
tabname='table' option_list='rownode=tr,colnode=td';
```

The table are displayed as:

Name	Origin	Description
Huntsman	Bath, UK	Wonderful hop, light alcohol
Tuborg	Danmark	In small bottles

However, you can deal with tables even closer to the HTML model. For example the *coffee.htm* file:

```
<TABLE summary="This table charts the number of cups of coffe
                consumed by each senator, the type of coffee (decaf
                or regular), and whether taken with sugar.">
  <CAPTION>Cups of coffee consumed by each senator</CAPTION>
  <TR>
    <TH>Name</TH>
    <TH>Cups</TH>
    <TH>Type of Coffee</TH>
    <TH>Sugar?</TH>
  </TR>
  <TR>
    <TD>T. Sexton</TD>
    <TD>10</TD>
    <TD>Espresso</TD>
    <TD>No</TD>
  </TR>
  <TR>
    <TD>J. Dinnen</TD>
    <TD>5</TD>
    <TD>Decaf</TD>
    <TD>Yes</TD>
  </TR>
</TABLE>
```

Here column values are directly represented by the TD tag text. You cannot declare them as tags nor as attributes. In addition, they are not located using their name but by their position within the row. Here is how to declare such a table to CONNECT:

```
CREATE TABLE coffee (
  `Name` CHAR(16),
  `Cups` INT(8),
  `Type` CHAR(16),
  `Sugar` CHAR(4))
ENGINE=CONNECT table_type=XML file_name='coffee.htm'
tabname='TABLE' header=1 option_list='Coltype=HTML';
```

You specify the fact that columns are located by position by setting the_Coltype_ option to 'HTML'. Each column position (0 based) are the value of the *flag* column parameter that is set by default in sequence. Now we are able to display the table:

Name	Cups	Type	Sugar
T. Sexton	10	Espresso	No
J. Dinnen	5	Decaf	Yes

Note 1: We specified '`header=n`' in the create statement to indicate that the first n rows of the table are not data rows and should be skipped.

Note 2: In this last example, we did not specify the node names using the Rownode and Colnode options because when *Coltype* is set to 'HTML' they default to '`Rownode=TR`' and '`Colnode=TD`'.

Note 3: The *Coltype* option is a word only the first character of which is significant. Recognized values are:

T(ag) or N(ode)	Column names match a tag name (the default).
A(ttribute) or @	Column names match an attribute name.
H(tml) or C(ol) or P(os)	Column are retrieved by their position.

New File Setting

Some create options are used only when creating a table on a new file, for instance, when inserting into a file that does not exist yet. When specified, the 'Header' option will create a header row with the name of the table columns.

This is chiefly useful for HTML tables to be displayed on a web browser.

Some new list-options are used in this context:

Encoding	The encoding of the new document, defaulting to UTF-8.
Attribute	A list of ‘attname=attvalue’ separated by ‘;’ to add to the table node.
HeadAttr	An attribute list to be added to the header row node.

Let us see for instance, the following create statement:

```
CREATE TABLE handlers (
  handler CHAR(64),
  VERSION CHAR(20),
  author CHAR(64),
  description CHAR(255),
  maturity CHAR(12))
ENGINE=CONNECT table_type=XML file_name='handlers.htm'
tabname='TABLE' header=yes
option_list='coltype=HTML,encoding=ISO-8859-1,
attribute=border=1;cellpadding=5,headattr=bgcolor=yellow';
```

Supposing the table file does not exist yet, the first insert into that table, for instance by the following statement:

```
INSERT INTO handlers SELECT plugin_name, plugin_version,
  plugin_author, plugin_description, plugin_maturity FROM
  information_schema.plugins WHERE plugin_type = 'DAEMON';
```

will generate the following file:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<!-- Created by CONNECT Version 3.05.0005 August 17, 2012 -->
<TABLE border="1" cellpadding="5">
  <TR bgcolor="yellow">
    <TH>handler</TH>
    <TH>version</TH>
    <TH>author</TH>
    <TH>description</TH>
    <TH>maturity</TH>
  </TR>
  <TR>
    <TD>Maria</TD>
    <TD>1.5</TD>
    <TD>Monty Program Ab</TD>
    <TD>Compatibility aliases for the Aria engine</TD>
    <TD>Gamma</TD>
  </TR>
</TABLE>
```

This file can be used to display the table on a web browser (encoding should be `ISO-8859-x`)

handler	version	author	description	maturity
Maria	1.5	Monty Program Ab	Compatibility aliases for the Aria engine	Gamma

Note: The XML document encoding is generally specified in the XML header node and can be different from the DATA_CHARSET, which is always UTF-8 for XML tables. Therefore the table DATA_CHARSET character set should be unspecified, or specified as UTF8. The Encoding specification is useful only for new XML files and ignored for existing files having their encoding already specified in the header node.

Notes

1. ↑ CONNECT does not claim to be able to deal with any XML document. Besides, those that can usefully be processed for data analysis are likely to have a structure that can easily be transformed into a table.
2. ↑ With libxml2, sub tags text can be separated by 0 or several blanks depending on the structure and indentation of the data file.
3. ↑ This may cause some rows to be lost because an eventual where clause on the “multiple” column is applied only on the limited number of retrieved rows.

CONNECT Zipped File Tables

Connect can work on table files that are compressed in one or several zip files.

The specific options used when creating tables based on zip files are:

Table Option	Type	Description
ZIPPED	Boolean	Required to be set as true.
ENTRY*	String	The optional name or pattern of the zip entry or entries to be used with the table. If not specified, all entries or only the first one are used depending on the mulentries option setting.
MULENTRIES*	Boolean	True if several entries are part of the table. If not specified, it defaults to false if the entry option is not specified. If the entry option is specified, it defaults to true if the entry name contains wildcard characters or false if it does not.
APPEND*	Boolean	Used when creating new zipped tables (see below)
LOAD*	String	Used when creating new zipped tables (see below)

Options marked with a ‘*’ must be specified in the option list.

Examples of use:

Example 1: Single CSV File Included in a Single ZIP File

Let’s suppose you have a CSV file from which you would create a table by:

```
ENGINE=connect table_type=CSV file_name='E:/Data/employee.csv'
CREATE TABLE emp
... optional COLUMN definition
sep_char=';' header=1;
```

If the CSV file is included in a ZIP file, the CREATE TABLE becomes:

```
CREATE TABLE empzip
... optional column definition
ENGINE=connect table_type=CSV file_name='E:/Data/employee.zip'
sep_char=';' header=1 zipped=1 option_list='Entry=emp.csv';
```

The *file_name* option is the name of the zip file. The *entry* option is the name of the entry inside the zip file. If there is only one entry file inside the zip file, this option can be omitted.

Example 2: Several CSV Files Included in a Single ZIP File

If the table is made from several files such as emp01.csv, emp02.csv, etc., the standard create table would be:

```
CREATE TABLE empmul (
... required column definition
) ENGINE=connect table_type=CSV file_name='E:/Data/emp*.csv'
sep_char=';' header=1 multiple=1;
```

But if these files are all zipped inside a unique zip file, it becomes:

```
CREATE TABLE empzmul
... required column definition
ENGINE=connect table_type=CSV file_name='E:/Data/emp.zip'
sep_char=';' header=1 zipped=1 option_list='Entry=emp*.csv';
```

Here the *entry* option is the pattern that the files inside the zip file must match. If all entry files are ok, the *entry* option can be omitted but the Boolean option *mulentries* must be specified as true.

Example 3: Single CSV File included in Multiple ZIP Files (Without considering subfolders)

If the table is created on several zip files, it is specified as for all other multiple tables:

```
CREATE TABLE zempmul (
... required column definition
) ENGINE=connect table_type=CSV file_name='E:/Data/emp*.zip'
sep_char=';' header=1 multiple=1 zipped=yes
option_list='Entry=employee.csv';
```

Here again the *entry* option is used to restrict the entry file(s) to be used inside the zip files and can be omitted if all are ok.

The column descriptions can be retrieved by the discovery process for table types allowing it. It cannot be done for multiple tables or multiple entries.

A catalog table can be created by adding *catfunc=columns*. This can be used to show the column definitions of multiple tables. *Multiple* must be set to false and the column definitions are the ones of the first table or entry.

This first implementation has some restrictions:

1. Zipped tables are read-only. UPDATE and DELETE are not supported. However, INSERT is supported in a specific way when making tables.
2. The inside files are decompressed into memory. Memory problems may arise with huge files.
3. Only file types that can be handled from memory are eligible for this. This includes DOS, FIX, BIN, CSV, FMT, DBF, JSON, and XML table types, as well as types based on these such as XCOL, OCCUR and PIVOT.

Optimization by indexing or block indexing is possible for table types supporting it. However, it applies to the uncompressed table. This means that the whole table is always uncompressed.

Partitioning is also supported. See how to do it in the section about partitioning.

Creating New Zipped Tables

Tables can be created to access already existing zip files. However, is it also possible to make the zip file from an existing file or table. Two ways are available to make the zip file:

Insert Method

insert can be used to make the table file for table types based on records (this excludes DBF, XML and JSON when pretty is not 0). However, the current implementation of the used package (minizip) does not support adding to an already existing zip entry. This means that when executing an insert statement the inserted records are not added but replace the existing ones. CONNECT protects existing data by not allowing such inserts, Therefore, only three ways are available to do so:

1. Using only one insert statement to make the whole table. This is possible only for small tables and is principally useful when making tests.
2. Making the table from the data of another table. This can be done by executing an “insert into table select * from another_table” or by specifying “as select * from another_table” in the create table statement.
3. Making the table from a file whose format enables to use the “load data infile” statement.

To add a new entry in an existing zip file, specify “append=YES” in the option list. When inserting several entries, use ALTER to specify the required options, for instance:

```
CREATE TABLE znumul (
Chiffre INT(3) NOT NULL,
Lettre CHAR(16) NOT NULL)
ENGINE=CONNECT table_type=CSV
file_name='C:/Data/FMT/mnum.zip' header=1 lrecl=20 zipped=1
option_list='Entry=Num1';
INSERT INTO znumul SELECT * FROM num1;
ALTER TABLE znumul option_list='Entry=Num2,Append=YES';
INSERT INTO znumul SELECT * FROM num2;
ALTER TABLE znumul option_list='Entry=Num3,Append=YES';
INSERT INTO znumul SELECT * FROM num3;
ALTER TABLE znumul option_list='Entry=Num*,Append=YES';
SELECT * FROM znumul;
```

The last ALTER is needed to display all the entries.

File Zipping Method

This method enables to make the zip file from another file when creating the table. It applies to all table types including DBF, XML and JSON. It is specified in the create table statement with the load option:

```
CREATE TABLE XSERVZIP (
NUMERO VARCHAR(4) NOT NULL,
LIEU VARCHAR(15) NOT NULL,
CHEF VARCHAR(5) NOT NULL,
FUNCTION VARCHAR(12) NOT NULL,
NOM VARCHAR(21) NOT NULL)
ENGINE=CONNECT table_type=XML file_name='E:/Xml/perso.zip' zipped=1
option_list='entry=services,load=E:/Xml/serv2.xml';
```

When executing this statement, the *serv2.xml* file are zipped as /perso.zip*. The entry name can be specified or defaults to the source file name.*

If the column descriptions are specified, the table can be used later to read from the zipped table, but they are not used when creating the zip file. Thus, a fake column (there must be one) can be specified and another table created to read the zip file. This one can take advantage of the discovery process to avoid providing the columns description for table types allowing it. For instance:

```
CREATE TABLE mkzq (whatever INT)
ENGINE=connect table_type=DBF zipped=1
file_name='C:/Data/EAUX/dbf/CQUART.ZIP'
option_list='Load=C:/Data/EAUX/dbf/CQUART.DBF';
```

```
CREATE TABLE zquart
ENGINE=connect table_type=DBF zipped=1
file_name='C:/Data/EAUX/dbf/CQUART.ZIP';
```

It is also possible to create a multi-entries table from several files:

```
CREATE TABLE znewcities (
  _id CHAR(5) NOT NULL,
  city CHAR(16) NOT NULL,
  lat DOUBLE(18,6) NOT NULL `FIELD_FORMAT`='loc:[0]',
  lng DOUBLE(18,6) NOT NULL `FIELD_FORMAT`='loc:[1]',
  pop INT(6) NOT NULL,
  state CHAR(2) NOT NULL
) ENGINE=CONNECT TABLE_TYPE=JSON FILE_NAME='E:/Json/newcities.zip' ZIPPED=1 LRECL=1000
OPTION_LIST='Load=E:/Json/city_*.json,mulentries=YES,pretty=0';
```

Here the files to load are specified with wildcard characters and the *mulentries* options must be specified. However, the *entry* option must not be specified, entry names are made from the file names. Provide a fake column description if the files have different column layout, but specific tables will have to be created to read each of them.

ZIP Table Type

A ZIP table type is also available. It is not meant to read the inside files but to display information about the zip file contents. For instance:

```
CREATE TABLE xzipinfo2 (
entry VARCHAR(256)NOT NULL,
cmpsize BIGINT NOT NULL flag=1,
uncsize BIGINT NOT NULL flag=2,
method INT NOT NULL flag=3,
date DATETIME NOT NULL flag=4)
ENGINE=connect table_type=ZIP file_name='E:/Data/Json/cities.zip';
```

This will display the name, compressed size, uncompressed size, and compress method of all entries inside the zip file. Column names are irrelevant; these are flag values that mean what information to retrieve.

It is possible to retrieve this information from several zip files by specifying the multiple option:

```
CREATE TABLE TestZip1 (
entry VARCHAR(260)NOT NULL,
cmpsize BIGINT NOT NULL flag=1,
uncsize BIGINT NOT NULL flag=2,
method INT NOT NULL flag=4,
date DATETIME NOT NULL flag=4,
zipname VARCHAR(256) special='FILEID')
ENGINE=connect table_type=ZIP multiple=1
file_name='C:/Data/Ziptest/CCAM06300_DBF_PART*.zip';
```

Here we added the special column zipname to get the name of the zip file for each entry.

Inward and Outward Tables

There are two broad categories of file-based CONNECT tables. Inward and Outward. They are described below.

Outward Tables

Tables are “outward” when their file name is specified in the CREATE TABLE statement using the *file_name* option.

Firstly, remember that CONNECT implements MED (Management of External Data). This means that the “true” CONNECT tables – “outward tables” – are based on data that belongs to files that can be produced by other applications or data imported from another DBMS.

Therefore, their data is “precious” and should not be modified except by specific commands such as INSERT, UPDATE, or DELETE. For other commands such as CREATE, DROP, or ALTER their data is never modified or erased.

Outward tables can be created on existing files or external tables. When they are dropped, only the local description is dropped, the file or external table is not dropped or erased. Also, DROP TABLE does not erase the indexes.

ALTER TABLE produces the following warning, as a reminder:

```
Warning (Code 1105): This is an outward table, table data were not modified.
```

If the specified file does not exist, it is created when data is inserted into the table. If a SELECT is issued before the file is created, the following error is produced:

```
Warning (Code 1105): Open(rb) error 2 on <file_path>: No such file or directory
```

Altering Outward Tables

When an ALTER TABLE is issued, it just modifies the table definition accordingly without changing the data. ALTER can be used safely to, for instance, modify options such as MAPPED, HUGE or READONLY but with extreme care when modifying column definitions or order options because some column options such as FLAG should also be modified or may become wrong.

Changing the table type with ALTER often makes no sense. But many suspicious alterations can be acceptable if they are just meant to correct an existing wrong definition.

Translating a CONNECT table to another engine is fine but the opposite is forbidden when the target CONNECT table is not table based or when its data file exists (because when the target table data cannot be changed and if the source table is dropped, the table data would be lost). However, it can be done to create a new file-based tables when its file does not exist or is void.

Creating or dropping indexes is accepted because it does not modify the table data. However, it is often unsafe to do it with an ALTER TABLE statement that does other modifications.

Of course, all changes are acceptable for empty tables.

Note: Using outward tables requires the FILE privilege.

Inward Tables

A special type of file-based CONNECT tables are “inward” tables. They are file-based tables whose file name is not specified in the CREATE TABLE statement (no *file_name* option).

Their file are located in the current database directory and their name will default to tablename.type where tablename is the table name and type is the table type folded to lower case. When they are created without using a `CREATE TABLE ... SELECT ...` statement, an empty file is made at create time and they can be populated by further inserts.

They behave like tables of other storage engines and, unlike outward CONNECT tables, they are erased when the table is dropped. Of course they should not be read-only to be usable. Even though their utility is limited, they can be used for testing purposes or when the user does not have the FILE privilege.

Altering Inward Tables

One thing to know, because CONNECT builds indexes in a specific way, is that all index modifications are done using an “in-place” algorithm – meaning not using a temporary table. This is why, when indexing is specified in an ALTER TABLE statement containing other changes that cannot be done “in-place”, the statement cannot be executed and raises an error.

Converting an inward table to an outward table, using an `ALTER TABLE` statement specifying a new file name and/or a new table type, is restricted the same way it is when converting a table from another engine to an outward table. However there are no restrictions to convert another engine table to a CONNECT inward table.

This page is licensed: CC BY-SA / Gnu FDL

CONNECT Security

The use of the CONNECT engine requires the FILE privilege for "outward" tables. This should not be an important restriction. The use of CONNECT "outward" tables on a remote server seems of limited interest without knowing the files existing on it and must be protected anyway. On the other hand, using it on the local client machine is not an issue because it is always possible to create locally a user with the `FILE` privilege.

CONNECT System Variables

> **Warning:**
>
> This storage engine has been deprecated.

This page documents system variables related to the CONNECT storage engine. See Server System Variables for instructions on setting them.

See also the Full list of MariaDB options, system and status variables.

`connect_class_path`

- Description: Java class path
- Command line: `--connect-class-path=value`
- Scope: Global
- Dynamic:
- Data Type: `string`
- Default Value:

`connect_cond_push`

- Description: Enable condition pushdown
- Command line: `--connect-cond-push={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`connect_conv_size`

- Description: The size of the VARCHAR created when converting from a TEXT type. See connect_type_conv.
- Command line: `--connect-conv-size=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - = MariaDB 10.4.8: `1024`
  - <= MariaDB 10.4.7: `8192`
- Range: `0` to `65500`

`connect_default_depth`

- Description: Default depth used by Json, XML and Mongo discovery.
- Command line: `--connect-default-depth=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `5`
- Range: `-1` to `16`
- Introduced: MariaDB 10.5.7, MariaDB 10.4.16

`connect_default_prec`

- Description: Default precision used for doubles.
- Command line: `--connect-default-prec=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `6`
- Range: `0` to `16`
- Introduced: MariaDB 10.5.9, MariaDB 10.4.18

`connect_enable_mongo`

- Description: Enable the Mongo table type.
- Command line: `--connect-enable-mongo={0|1}`
- Scope: Global, Session
- Dynamic:
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.3.2, MariaDB 10.2.9
- Removed: MariaDB 10.3.3

`connect_exact_info`

- Description: Whether the CONNECT engine should return an exact record number value to information queries. It is OFF by default because this information can take a very long time for large variable record length tables or for remote tables, especially if the remote server is not available. It can be set to ON when exact values are desired, for instance when querying the repartition of rows in a partition table.
- Command line: `--connect-exact-info={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`connect_force_bson`

- Description: Force using BSON for JSON tables. Starting with these releases, the internal way JSON was parsed and handled was changed. The main advantage of the new way is to reduce the memory required to parse JSON (from 6 to 10 times the size of the JSON source to now only 2 to 4 times). However, this is in Beta

mode and JSON tables are still handled using the old mode. To use the new mode, tables should be created with TABLE_TYPE=BSON, or by setting this session variable to 1 or ON. Then, all JSON tables are handled as BSON. This is temporary until the new way replaces the old way by default.

- Command line: `--connect-force-bson={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.5.9, MariaDB 10.4.18

`connect_indx_map`

- Description: Enable file mapping for index files. To accelerate the indexing process, CONNECT makes an index structure in memory from the index file. This can be done by reading the index file or using it as if it was in memory by "file mapping". Set to 0 (file read, the default) or 1 (file mapping).
- Command line: `--connect-indx-map=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`connect_java_wrapper`

- Description: Java wrapper.
- Command line: `--connect-java-wrapper=val`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `string`
- Default Value: `wrappers/JdbcInterface`

`connect_json_all_path`

- Description: Discovery to generate json path for all columns if ON (the default) or do not when the path is the column name.
- Command line: `--connect-json-all-path={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Data Type: `boolean`
- Default Value: `ON`
- Introduced: MariaDB 10.5.7, MariaDB 10.4.16

`connect_json_grp_size`

- Description: Max number of rows for JSON aggregate functions.
- Command line: `--connect-json-grp-size=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`

- Default Value: `50` (>= Connect 1.7.0003), `10` (<= Connect 1.7.0002)
- Range: `1` to `2147483647`

`connect_json_null`

- Description: Representation of JSON null values.
- Command line: `--connect-json-null=value`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `string`
- Default Value: `<null>`

`connect_jvm_path`

- Description: Path to JVM library.
- Command line: `--connect-jvm_path=value`
- Scope: Global
- Dynamic:
- Data Type: `string`
- Default Value:

`connect_type_conv`

- Description: Determines the handling of TEXT columns.
  - `NO`: The default until Connect 1.06.005, no conversion takes place, and a TYPE_ERROR is returned, resulting in a “not supported” message.
  - `YES`: The default from Connect 1.06.006. The column is internally converted to a column declared as VARCHAR(n), `n` being the value of connect_conv_size.
  - `FORCE` (>= Connect 1.06.006): Also convert ODBC blob columns to TYPE_STRING.
  - `SKIP`: No conversion. When the column declaration is provided via Discovery (meaning the CONNECT table is created without a column description), this column is not generated. Also applies to ODBC tables.
- Command line: `--connect-type-conv=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `enum`
- Valid Values: `NO`, `YES`, `FORCE` or `SKIP`
- Default Value: `YES`

`connect_use_tempfile`

- Description:
  - `NO`: The first algorithm is always used. Because it can cause errors when updating variable record length tables, this value should be set only for testing.
  - `AUTO`: This is the default value. It leaves CONNECT to choose the algorithm to use. Currently it is equivalent to `NO`, except when updating variable record length tables (DOS, CSV or FMT) with file mapping forced to OFF.
  - `YES`: Using a temporary file is chosen with some exceptions. These are when file mapping is ON, for VEC tables and when deleting from DBF tables (soft delete). For variable record length tables, file mapping is forced to OFF.
  - `FORCE`: Like YES but forces file mapping to be OFF for all table types.

    - `TEST` : Reserved for CONNECT development.
- Command line: `--connect-use-tempfile=#`
- Scope: Session
- Dynamic: Yes
- Data Type: `enum`
- Default Value: `AUTO`

`connect_work_size`

- Description: Size of the CONNECT work area used for memory allocation. Permits allocating a larger memory sub-allocation space when dealing with very large if sub-allocation fails. If the specified value is too big and memory allocation fails, the size of the work area remains but the variable value is not modified and should be reset.
- Command line: `--connect-work-size=#`
- Scope: Global, Session (Session-only from CONNECT 1.03.005)
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `67108864`
- Range: `4194304` upwards, depending on the physical memory size

`connect_xtrace`

- Description: Console trace value. Set to `0` (no trace), or to other values if a console tracing is desired. Note that to test this handler, MariaDB should be executed with the –console parameter because CONNECT prints some error and trace messages on the console. In some Linux versions, this is re-routed into the error log file. Console tracing can be set on the command line or later by names or values. Valid values (from Connect 1.06.006) include:
    - `0` : No trace
    - `YES` or `1` : Basic trace
    - `MORE` or `2` : More tracing
    - `INDEX` or `4` : Index construction
    - `MEMORY` or `8` : Allocating and freeing memory
    - `SUBALLOC` or `16` : Sub-allocating in work area
    - `QUERY` or `32` : Constructed query sent to external server
    - `STMT` or `64` : Currently executing statement
    - `HANDLER` or `128` : Creating and dropping CONNECT handlers
    - `BLOCK` or `256` : Creating and dropping CONNECT objects
    - `MONGO` or `512` : Mongo and REST (from Connect 1.06.0010) tracing :
    - `set global connect_xtrace=0; No trace`
    - `set global connect_xtrace='YES'; By name`
    - `set global connect_xtrace=1; By value`
    - `set global connect_xtrace='QUERY,STMT'; By name`
    - `set global connect_xtrace=96; By value`
    - `set global connect_xtrace=1023; Trace all`
- Command line: `--connect-xtrace=#`
- Scope: Global
- Dynamic: Yes

- Data Type: `set`
- Default Value: `0`
- Valid Values: See description

Adding the REST Feature as a Library Called by an OEM Table

If you are using a version of MariaDB that does not support REST, this is how the REST feature can be added as a library called by an OEM table.

Before making the REST OEM module, the Microsoft Casablanca package must be installed as for compiling MariaDB from source.

Even if this module is to be used with a binary distribution, you need some CONNECT source files in order to successfully make it. It is made with four files existing in the version 1.06.0010 of CONNECT: tabrest.cpp, restget.cpp, tabrest.h and mini-global.h. It also needs the CONNECT header files that are included in `tabrest.cpp` and the ones they can include. This can be obtained by going to a recent download site of a version of MariaDB that includes the REST feature, downloading the MariaDB source file `tar.gz` and extracting from it the CONNECT sources files in a directory that are added to the additional source directories if it is not the directory containing the above files.

On Windows, use a recent version of Visual Studio. Make a new empty DLL project and add the source files `tabrest.cpp` and `restget.cpp`. Visual studio should automatically generate all necessary connections to the `cpprest` SDK. Just edit the properties of the project to add the additional include directory (the one where the CONNECT source was downloaded) et the link to the ha_connect.lib of the binary version of MariaDB (in the same directory than `ha_connect.dll` in your binary distribution). Add the preprocessor definition `XML_SUPPORT`. Also set in the linker input page of the project property the Module definition File to the rest.def file (with its full path) also existing in the CONNECT source files. If you are making a debug configuration, make sure that in the C/C++ Code generation page the Runtime library line specifies Multi-threaded Debug DLL (/MDd) or your server crashes when using the feature.

This is not really simple but it is nothing compared with Linux! Someone having made an OEM module for its own application have written:

For whatever reason, g++ / ld on Linux are both extremely picky about what they will and won't consider a *"library"* for linking purposes. In order to get them to recognize and therefore find `ha_connect.so` as a "valid" linkable library, `ha_connect.so` must exist in a directory whose path is in `/etc/ld.so.conf` or `/etc/ld.so.conf.d/ha_connect.conf` *AND* its filename must begin with "lib".

On Fedora, you can make a link to ha_connect.so by:

```
$ sudo ln -s /..path to../ha_connect.so /usr/lib64/libconnect.so
```

This provides a library whose name begins with "lib". It was made in `/usr/lib64/` because it was the directory of the libcpprest.so Casablanca library. This solved the need of a file in `/etc/ld.so.conf.d` as this was already done for the `cpprest` library. Note that the -s parameter is a must, without it all sort of nasty errors are met when using the feature.

Then compile and install the OEM module with:

```
$ makdir oem
$ cd oem
$ makedir Release
$ make -f oemrest.mak
$ sudo cp rest.so /usr/local/mysql/lib/plugin
```

The `oemrest.mak` file:

```
#LINUX
CPP = g++
LD = g++
OD = ./Release/
SD = /home/olivier/MariaDB/server/storage/connect/
CD =/usr/lib64
# flags to compile object files that can be used in a dynamic library
CFLAGS= -Wall -c -O3 -std=c++11 -fPIC -fno-rtti -I$(SD) -DXML_SUPPORT
# Replace -03 by -g for debug
LDFLAGS = -L$(CD) -lcpprest -lconnect

# Flags to create a dynamic library.
DYNLINKFLAGS = -shared
# on some platforms, use '-G' instead.

# REST library's archive file
OEMREST = rest.so

SRCS_CPP = $(SD)tabrest.cpp $(SD)restget.cpp
OBJS_CPP = $(OD)tabrest.o $(OD)restget.o

# top-level rule
all: $(OEMREST)

$(OEMREST): $(OBJS_CPP)
  $(LD) $(OBJS_CPP) $(LDFLAGS) $(DYNLINKFLAGS) -o $@

#CPP Source files
$(OD)tabrest.o:   $(SD)tabrest.cpp   $(SD)mini-global.h $(SD)global.h $(SD)plgdbsem.h $(SD)xtable.h
$(SD)filamtxt.h $(SD)plgxml.h $(SD)tabdos.h  $(SD)tabfmt.h $(SD)tabjson.h $(SD)tabrest.h $(SD)tabxml.h
  $(CPP) $(CFLAGS) -o $@ $(SD)$(*F).cpp
$(OD)restget.o:   $(SD)restget.cpp   $(SD)mini-global.h $(SD)global.h
  $(CPP) $(CFLAGS) -o $@ $(SD)$(*F).cpp

# clean everything
clean:
  $(RM) $(OBJS_CPP) $(OEMREST)
```

The SD and CD variables are the directories of the CONNECT source files and the one containing the libcpprest.so lib. They can be edited to match those on your machine OD is the directory that was made to contain the object files.

A very important flag is -fno-rtti. Without it you would be in big trouble.

The resulting module, for instance rest.so or rest.dll, must be placed in the plugin directory of the MariaDB server. Then, you are able to use NoSQL tables simply replacing in the CREATE TABLE statement the TABLE_TYPE option =JSON or XML by TABLE_TYPE=OEM SUBTYPE=REST MODULE='rest.(so|dll)'. Actually, the module name, here supposedly 'rest', can be anything you like.

The file type is JSON by default. If not, it must be specified like this:

```
OPTION_LIST='Ftype=XML'
```

To be added to the create table statement. For instance:

```
CREATE  TABLE webw
ENGINE=CONNECT TABLE_TYPE=OEM MODULE='Rest.dll' SUBTYPE=REST
FILE_NAME='weatherdata.xml'
HTTP='https://samples.openweathermap.org/data/2.5/forecast?
q=London,us&mode=xml&appid=b6907d289e10d714a6e88b30761fae22'
OPTION_LIST='Ftype=XML,Depth=3,Rownode=weatherdata';
```

Note: this last example returns an XML file whose format was not recognized by old CONNECT versions. It is here the reason of the option ‘Rownode=weatherdata’.

If you have trouble making the module, you can post an issue on JIRA.

Compiling JSON UDFs in a Separate Library

Although the JSON UDFs can be included in the CONNECT library module, there are cases when you may need to have them in a separate library.

This is when CONNECT is compiled embedded, or if you want to test or use these UDFs with other MariaDB versions not including them.

To make it, you need to have access to the most recent MariaDB source code. Then, make a project containing these files:

1. jsonudf.cpp
2. json.cpp
3. value.cpp
4. osutil.c
5. plugutil.cpp
6. maputil.cpp
7. jsonutil.cpp

`jsonutil.cpp` is not distributed with the source code, you will have to make it from the following:

```
#include "my_global.h"
#include "mysqld.h"
#include "plugin.h"
#include <stdlib.h>
#include <string.h>
#include <stdio.h>
#include <errno.h>

#include "global.h"

extern "C" int GetTraceValue(void) { return 0; }
uint GetJsonGrpSize(void) { return 100; }

/***********************************************************************/
/*  These replace missing function of the (not used) DTVAL class.      */
/***********************************************************************/
typedef struct _datpar   *PDTP;
PDTP MakeDateFormat(PGLOBAL, PSZ, bool, bool, int) { return NULL; }
int ExtractDate(char*, PDTP, int, int val[6]) { return 0; }

#ifdef __WIN__
my_bool CloseFileHandle(HANDLE h)
{
    return !CloseHandle(h);
} /* end of CloseFileHandle */

#else  /* UNIX */
my_bool CloseFileHandle(HANDLE h)
{
    return (close(h)) ? TRUE : FALSE;
}  /* end of CloseFileHandle */

int GetLastError()
{
    return errno;
}  /* end of GetLastError */

#endif  // UNIX

/***********************************************************************/
/*  Program for sub-allocating one item in a storage area.             */
/*  Note: This function is equivalent to PlugSubAlloc except that in   */
/*  case of insufficient memory, it returns NULL instead of doing a    */
/*  long jump. The caller must test the return value for error.        */
/***********************************************************************/
void *PlgDBSubAlloc(PGLOBAL g, void *memp, size_t size)
{
  PPOOLHEADER pph;                       // Points on area header.

  if (!memp)    //  Allocation is to be done in the Sarea
    memp = g->Sarea;

  size = ((size + 7) / 8) * 8;  /* Round up size to multiple of 8 */
  pph = (PPOOLHEADER)memp;

  if ((uint)size > pph->FreeBlk) { /* Not enough memory left in pool */
    sprintf(g->Message,
     "Not enough memory in Work area for request of %d (used=%d free=%d)",
            (int)size, pph->To_Free, pph->FreeBlk);
    return NULL;
  } // endif size

  // Do the suballocation the simplest way
  memp = MakePtr(memp, pph->To_Free);   // Points to sub_allocated block
  pph->To_Free += size;                 // New offset of pool free block
  pph->FreeBlk -= size;                 // New size   of pool free block
```

```
  return (memp);
} // end of PlgDBSubAlloc
```

You can create the file by copy/paste from the above.

Set all the additional include directories to the MariaDB include directories used in plugin compiling plus the reference of the storage/connect directories, and compile like any other UDF giving any name to the made library module (I used `jsonudf.dll` on Windows).

Then you can create the functions using this name as the soname parameter.

There are some restrictions when using the UDFs this way:

- The connect_json_grp_size variable cannot be accessed. The group size is set and retrieved using the jsonset_grp_size and jsonget_grp_size functions (previously 100).
- In case of error, warnings are replaced by messages sent to stderr.
- No trace.

Making the GetRest Library

To enable the REST feature with binary distributions of MariaDB, the function calling the cpprestsdk package is not included in CONNECT, thus allowing CONNECT normal operation when the `cpprestsdk` package is not installed. Therefore, it must be compiled separately as a library (so or dll) that are loaded by CONNECT when needed.

This library will contain only one file shown here:

```
/************* Restget C++ Program Source Code File (.CPP) *************/
/* Adapted from the sample program of the Casablanca tutorial.         */
/* Copyright Olivier Bertrand 2019.                                    */
/***********************************************************************/
#include <cpprest/filestream.h>
#include <cpprest/http_client.h>

using namespace utility::conversions; // String conversions utilities
using namespace web;                  // Common features like URIs.
using namespace web::http;            // Common HTTP functionality
using namespace web::http::client;    // HTTP client features
using namespace concurrency::streams; // Asynchronous streams

typedef const char* PCSZ;

extern "C" int restGetFile(char* m, bool xt, PCSZ http, PCSZ uri, PCSZ fn);

/***********************************************************************/
/*  Make a local copy of the requested file.                           */
/***********************************************************************/
int restGetFile(char *m, bool xt, PCSZ http, PCSZ uri, PCSZ fn)
{
  int  rc = 0;
  auto fileStream = std::make_shared<ostream>();

  if (!http || !fn) {
        strcpy(m, "Missing http or filename");
        return 2;
  } // endif

    if (xt)
        fprintf(stderr, "restGetFile: fn=%s\n", fn);

  // Open stream to output file.
  pplx::task<void> requestTask = fstream::open_ostream(to_string_t(fn))
    .then([=](ostream outFile) {
      *fileStream= outFile;

            if (xt)
                fprintf(stderr, "Outfile isopen=%d\n", outFile.is_open());

      // Create http_client to send the request.
      http_client client(to_string_t(http));

      if (uri) {
        // Build request URI and start the request.
        uri_builder builder(to_string_t(uri));
        return client.request(methods::GET, builder.to_string());
      } else
        return client.request(methods::GET);
    })

    // Handle response headers arriving.
    .then([=](http_response response) {
            if (xt)
                fprintf(stderr, "Received response status code:%u\n",
                                  response.status_code());

      // Write response body into the file.
      return response.body().read_to_end(fileStream->streambuf());
    })

    // Close the file stream.
    .then([=](size_t n) {
            if (xt)
                fprintf(stderr, "Return size=%zu\n", n);

      return fileStream->close();
```

```
    });

  // Wait for all the outstanding I/O to complete and handle any exceptions
  try {
        if (xt)
            fprintf(stderr, "Waiting\n");

        requestTask.wait();
  } catch (const std::exception &e) {
        if (xt)
            fprintf(stderr, "Error exception: %s\n", e.what());

        sprintf(m, "Error exception: %s", e.what());
        rc= 1;
  } // end try/catch

    if (xt)
        fprintf(stderr, "restget done: rc=%d\n", rc);

  return rc;
} // end of restGetFile
```

This file exists in the source of CONNECT as `restget.cpp`. If you have no access to the source, use your favorite editor to make it by copy/pasting from the above.

Then, on Linux, compile the `GetRest.so` library:

```
g++ -o GetRest.so -O3 -Wall -std=c++11 -fPIC -shared restget.cpp -lcpprest
```

Note: You can replace `-O3` by `-g` to make a debug version.

This library should be placed where it can be accessed. A good place is the directory where the `libcpprest.so` is, for instance `/usr/lib64`. You can move or copy it there.

On windows, using Visual Studio, make an empty win32 dll project named GetRest and add it the above file. Also add it the module definition file `restget.def`:

```
LIBRARY REST
EXPORTS
   restGetFile     @1
```

> **Note:**
>
> This file must be specified in the property linker input page.

Once compiled, the release or debug versions can be copied in the `cpprestsdk` corresponding directories, bin or debug\bin.

That is all. It is a once-off job. Once done, it will work with all new MariaDB versions featuring CONNECT version 1.07.

Note: the xt tracing variable is true when connect_xtrace setting includes the value “MONGO” (512).

Caution: If your server crashes when using this feature, this is likely because the GetRest lib is linked to the wrong cpprestsdk lib (this may only apply on Windows). A Release version of GetRest must be linked to the release version of the `cpprestsdk lib` (cpprest_2_10.dll) but if you make a Debug version of GetRest, make sure it is linked to the Debug version of `cpprestsdk.lib` (or `cpprest_2_10d.dll`). This may be automatic if you use Visual Studio to make the GetRest.dll.

OEM Table Example

This is an example showing how an OEM table can be implemented.

The header File `my_global.h`:

```
/*****************************************************************/
/*  Definitions needed by the included files.                    */
/*****************************************************************/
#if !defined(MY_GLOBAL_H)
#define MY_GLOBAL_H
typedef unsigned int uint;
typedef unsigned int uint32;
typedef unsigned short ushort;
typedef unsigned long ulong;
typedef unsigned long DWORD;
typedef char *LPSTR;
typedef const char *LPCSTR;
typedef int BOOL;
#if defined(__WIN__)
typedef void *HANDLE;
#else
typedef int HANDLE;
#endif
typedef char *PSZ;
typedef const char *PCSZ;
typedef unsigned char BYTE;
typedef unsigned char uchar;
typedef long long longlong;
typedef unsigned long long ulonglong;
typedef char my_bool;
struct charset_info_st {};
typedef const charset_info_st CHARSET_INFO;
#define FALSE 0
#define TRUE  1
#define Item char
#define MY_MAX(a,b) ((a>b)?(a):(b))
#define MY_MIN(a,b) ((a<b)?(a):(b))
#endif // MY_GLOBAL_H
```

Note:

This is a fake `my_global.h` that just contains what is useful for the `jmgoem.cpp` source file.

The source File `jmgoem.cpp`:

```
/************* jmgoem C++ Program Source Code File (.CPP) *************/
/* PROGRAM NAME: jmgoem    Version 1.0                                  */
/*  (C) Copyright to the author Olivier BERTRAND          2017         */
/*  This program is the Java MONGO OEM module definition.              */

```

Compiling This OEM

To compile this OEM module, first make the two or three required files by copy/pasting from the above listings.

Even if this module is to be used with a binary distribution, you need some source files in order to successfully compile it. At least the CONNECT header files that are included in `jmgoem.cpp` and the ones they can include. This can be obtained by downloading the MariaDB source file tar.gz and extracting from it the CONNECT sources files in a directory that are added to the additional source directories if it is not the directory containing the above files.

The module must be linked to the `ha_connect.lib` of the binary version it will used with. Recent distributions add this lib in the plugin directory.

The resulting module, for instance `mongo.so` or `mongo.dll`, must be placed in the plugin directory of the MariaDB server. Then, you are able to use MONGO like tables simply replacing in the CREATE TABLE statement the option `TABLE_TYPE=MONGO` with `TABLE_TYPE=OEM SUBTYPE=MONGO MODULE='mongo.(so|dll)'`. Actually, the module name, here supposedly 'mongo', can be anything you like.

To implement for older versions that do not contain the MONGO type, you can add the corresponding source files, namely `javaconn.cpp`, `jmgfam.cpp`, `jmgoconn.cpp`, `mongo.cpp` and `tabjmg.cpp` that you should find in the CONNECT extracted source files if you downloaded a recent version. As they include `my_global.h`, this is the reason why the included file was named this way. In addition, your compiling should define `HAVE_JMGO` and `HAVE_JAVACONN`. Of course, this is possible only if `ha_connect.lib` is available.

Current Status of the CONNECT Handler

The CONNECT handler is a GA (stable) release. It was written starting both from an aborted project written for MySQL in 2004 and from the `DBCONNECT` program. It was tested on all the examples described in this document, and is distributed with a set of 53 test cases. Here is a not limited list of future developments:

1. Adding more table types.
2. Make more tests files (53 are already made)
3. Adding more data types, in particular unsigned ones (done for unsigned).
4. Supporting indexing on nullable and decimal columns.
5. Adding more optimize tools (block indexing, dynamic indexing, etc.) (done)
6. Supporting MRR (done)
7. Supporting partitioning (done)
8. Getting NOSQL data from the Net as answers from REST queries (done)

No programs are bug free, especially new ones. Please report all bugs or documentation errors using the means provided by MariaDB.

  } // enif neg

  Value->SetValue(fmon);
} // end of ReadColumn
```

tabfic.def

The file `tabfic.def` (required only on Windows):

```
LIBRARY     TABFIC
DESCRIPTION 'FIC files'
EXPORTS
   GetFIC       @1
```

JSON UDFs in a Separate Library

Although the JSON UDF's can be nicely included in the CONNECT library module, there are cases when you may need to have them in a separate library.

This is when CONNECT is compiled embedded, or if you want to test or use these UDF's with other MariaDB versions not including them.

To make it, you need to have access to the last MariaDB source code. Then, make a project containing these files:

1. jsonudf.cpp
2. json.cpp
3. value.cpp
4. osutil.c
5. plugutil.c
6. maputil.cpp
7. jsonutil.cpp

`jsonutil.cpp` is not distributed with the source code, you will have to make it from the following:

```
#include "my_global.h"
#include "mysqld.h"
#include "plugin.h"
#include <stdlib.h>
#include <string.h>
#include <stdio.h>
#include <errno.h>

#include "global.h"

extern "C" int GetTraceValue(void) { return 0; }
uint GetJsonGrpSize(void) { return 100; }

/***********************************************************************/
/*  These replace missing function of the (not used) DTVAL class.      */
/***********************************************************************/
typedef struct _datpar   *PDTP;
PDTP MakeDateFormat(PGLOBAL, PSZ, bool, bool, int) { return NULL; }
int ExtractDate(char*, PDTP, int, int val[6]) { return 0; }

#ifdef __WIN__
my_bool CloseFileHandle(HANDLE h)
{
    return !CloseHandle(h);
} /* end of CloseFileHandle */

#else  /* UNIX */
my_bool CloseFileHandle(HANDLE h)
{
    return (close(h)) ? TRUE : FALSE;
}  /* end of CloseFileHandle */

int GetLastError()
{
    return errno;
}  /* end of GetLastError */

#endif  // UNIX

/***********************************************************************/
/*  Program for sub-allocating one item in a storage area.             */
/*  Note: This function is equivalent to PlugSubAlloc except that in   */
/*  case of insufficient memory, it returns NULL instead of doing a    */
/*  long jump. The caller must test the return value for error.        */
/***********************************************************************/
void *PlgDBSubAlloc(PGLOBAL g, void *memp, size_t size)
{
  PPOOLHEADER pph;                       // Points on area header.

  if (!memp)    //  Allocation is to be done in the Sarea
    memp = g->Sarea;

  size = ((size + 7) / 8) * 8;  /* Round up size to multiple of 8 */
  pph = (PPOOLHEADER)memp;

  if ((uint)size > pph->FreeBlk) { /* Not enough memory left in pool */
    sprintf(g->Message,
     "Not enough memory in Work area for request of %d (used=%d free=%d)",
            (int)size, pph->To_Free, pph->FreeBlk);
    return NULL;
  } // endif size

  // Do the suballocation the simplest way
  memp = MakePtr(memp, pph->To_Free);   // Points to sub_allocated block
  pph->To_Free += size;                 // New offset of pool free block
  pph->FreeBlk -= size;                 // New size   of pool free block
```

```
  return (memp);
} // end of PlgDBSubAlloc
```

You can create the file by copy/paste from the above.

Set all the additional include directories to the MariaDB include directories used in plugin compiling plus the reference of the storage/connect directories, and compile like any other UDF giving any name to the made library module (I used `jsonudf.dll` on Windows)

Then you can create the functions using this name as the `soname` parameter.

There are some restrictions when using the UDF's this way:

- The `connect_json_grp_size` variable cannot be accessed. The group size is set to 100.
- In case of error, warnings are replaced by messages sent to stderr.
- No trace.

CSV

See CSV Overview.

The CSV Storage Engine stores data in comma-separated values format text files, making it easy to exchange data with other applications.

See Checking and Repairing CSV Tables.

Learn how to use CHECK TABLE and REPAIR TABLE to identify and fix corruptions in CSV tables, discarding rows from the first error onwards.

This page is licensed: CC BY-SA / Gnu FDL

CSV Overview

The CSV Storage Engine can read and append to files stored in CSV (comma-separated-values) format.

The CSV storage engine and logging to tables

The CSV storage engine is the default storage engine when using logging of SQL queries to tables.

```
mysqld --log-output=table
```

CSV Storage Engine files

When you create a table using the CSV storage engine, three files are created:

- `<table_name>.frm`
- `<table_name>.CSV`
- `<table_name>.CSM`

The `.frm` file is the table format file.

The `.CSV` file is a plain text file. Data you enter into the table is stored as plain text in comma-separated-values format.

The `.CSM` file stores metadata about the table such as the state and the number of rows in the table.

Limitations

- CSV tables do not support indexing.

- CSV tables cannot be partitioned.
- Columns in CSV tables must be declared as NOT NULL.
- No transactions.
- The original CSV-format does not enable IETF-compatible parsing of embedded quote and comma characters. From MariaDB 10.1.8, it is possible to do so by setting the IETF_QUOTES option when creating a table.

Examples

Forgetting to add NOT NULL:

```
CREATE TABLE csv_test (x INT, y DATE, z CHAR(10)) ENGINE=CSV;
ERROR 1178 (42000): The storage engine for the table doesn't support nullable columns
```

Creating, inserting and selecting:

```
CREATE TABLE csv_test (
  x INT NOT NULL, y DATE NOT NULL, z CHAR(10) NOT NULL
  ) ENGINE=CSV;
```

```
INSERT INTO csv_test VALUES
    (1,CURDATE(),'one'),
    (2,CURDATE(),'two'),
    (3,CURDATE(),'three');
```

```
SELECT * FROM csv_test;
+---+------------+-------+
| x | y          | z     |
+---+------------+-------+
| 1 | 2011-11-16 | one   |
| 2 | 2011-11-16 | two   |
| 3 | 2011-11-16 | three |
+---+------------+-------+
```

Viewing in a text editor:

```
$ cat csv_test.CSV
1,"2011-11-16","one"
2,"2011-11-16","two"
3,"2011-11-16","three"
```

Checking and Repairing CSV Tables

CSV tables support the CHECK TABLE and REPAIR TABLE statements.

`CHECK TABLE` marks the table as corrupt if it finds a problem, while `REPAIR TABLE` restores rows until the first corrupted row, discarding the rest.

Examples

```
CREATE TABLE csv_test (
  x INT NOT NULL, y DATE NOT NULL, z CHAR(10) NOT NULL
  ) ENGINE=CSV;

INSERT INTO csv_test VALUES
    (1,CURDATE(),'one'),
    (2,CURDATE(),'two'),
    (3,CURDATE(),'three');
```

```
SELECT * FROM csv_test;
+---+------------+-------+
| x | y          | z     |
+---+------------+-------+
| 1 | 2013-07-08 | one   |
| 2 | 2013-07-08 | two   |
| 3 | 2013-07-08 | three |
+---+------------+-------+
```

Using an editor, the actual file will look as follows

```
$ cat csv_test.CSV
1,"2013-07-08","one"
2,"2013-07-08","two"
3,"2013-07-08","three"
```

Let's introduce some corruption with an unwanted quote in the 2nd row:

```
1,"2013-07-08","one"
2","2013-07-08","two"
3,"2013-07-08","three"
```

```
CHECK TABLE csv_test;
+---------------+-------+----------+----------+
| Table         | Op    | Msg_type | Msg_text |
+---------------+-------+----------+----------+
| test.csv_test | check | error    | Corrupt  |
+---------------+-------+----------+----------+
```

We can repair this, but all rows from the corrupt row onwards are lost:

```
REPAIR TABLE csv_test;
+---------------+--------+----------+----------------------------------------+
| Table         | Op     | Msg_type | Msg_text                               |
+---------------+--------+----------+----------------------------------------+
| test.csv_test | repair | Warning  | Data truncated for column 'x' at row 2 |
| test.csv_test | repair | status   | OK                                     |
+---------------+--------+----------+----------------------------------------+

SELECT * FROM csv_test;
+---+------------+-----+
| x | y          | z   |
+---+------------+-----+
| 1 | 2013-07-08 | one |
+---+------------+-----+
```

DuckDB

DuckDB Storage Engine

> **Important:**
>
> **Experimental — for evaluation only.** The DuckDB storage engine is at **alpha** maturity. It is not yet merged into MariaDB Server `main`, not built into MariaDB releases, and not signed in any official package. Interfaces, configuration variables, behavior, and supported operations are subject to change. **Do not use in production.**

The DuckDB storage engine embeds DuckDB — a columnar, vectorized, in-process analytical database engine — inside MariaDB Server as a loadable plugin (`ha_duckdb.so`). Tables created with `ENGINE=DuckDB` store data in DuckDB's native columnar format, and queries against them are executed by the DuckDB engine. Cross-engine joins between DuckDB and other engines (e.g. InnoDB) are supported in a single `SELECT`.

The engine borrows its design from Alibaba's AliSQL DuckDB integration. The original code was heavily refactored to use MariaDB's handler API and plugin system, and the engine links against vanilla upstream DuckDB.

Use Cases

- **HTAP (Hybrid Transactional/Analytical Processing)** — InnoDB serves the transactional workload, DuckDB serves analytics, both in the same MariaDB server.
- **Ad-hoc analytical queries** — joins, aggregations, and window functions over large datasets without exporting data to a separate system.
- **Eliminating ETL** — the analytical engine runs in-process; no separate cluster or data-movement pipeline.

Architecture

DuckDB 1.5.2 is statically linked into a single plugin shared library (`ha_duckdb.so`) along with the built-in ICU and JSON extensions. The engine integrates with MariaDB via the standard `handler` API and adds a `select_handler` for full query pushdown.

Cross-engine queries (a single `SELECT` joining a `DuckDB` table with, for example, an `InnoDB` table) are handled as follows: the entire query is pushed down to DuckDB. When DuckDB references a non-DuckDB table, a callback re-enters the MariaDB query pipeline through a cooperative fiber to stream rows back. The MariaDB optimizer still chooses the access path on the non-DuckDB side, and DuckDB's optimizer drives join order, hashing, and aggregation.

Supported Platforms

- **OS:** Linux only.
- **Architectures:** `x86_64` and `aarch64` (ARM64).
- **Distributions** (auto-detected by the build script): Ubuntu 22.04, Ubuntu 24.04, Debian 12, Rocky Linux 8, Rocky Linux 9. Fedora 42 builds are produced by the MariaDB CI.
- **Compiler:** GCC 12 or later (C++17 required).
- **MariaDB Server:** the engine is being prepared for MariaDB 11.4. A merge into the mainline source tree and the shipping version are not yet final.

Installing

The engine is **not** included in MariaDB releases. There are two ways to obtain it: prebuilt test packages from MariaDB CI, or building from source.

Option 1: Prebuilt Test Packages

MariaDB CI builds the engine for several Linux distributions and publishes the artifacts on ci.mariadb.org. Each CI run has its own job number and a subdirectory per distribution and architecture, for example `amd64-ubuntu-2404-deb-autobake/` or `aarch64-ubuntu-2404-deb-autobake/`.

> **Warning:**
>
> These packages are **unsigned** and intended for testing only.

The CI job number is **not stable** across rebuilds. For the current job URL, see the blog posts under See also.

Example for Ubuntu 24.04 (`amd64`), with a current job number `<JOB>`:

```
# Fetch the .deb files for the job
wget -r -np -nH --cut-dirs=2 -A '*.deb' \
  https://ci.mariadb.org/<JOB>/amd64-ubuntu-2404-deb-autobake/

# Install the server and the DuckDB plugin package
sudo dpkg -i mariadb-server*.deb mariadb-plugin-duckdb*.deb || sudo apt -f install
```

Option 2: Build From Source

The engine integration lives on the `11.4` branch of `MariaDB/server`. The engine source resides in the server repository under `storage/duckdb/`; a helper script there handles dependency installation and the build.

```
git clone --recurse-submodules -b 11.4 \
  https://github.com/MariaDB/server.git mariadb-server
cd mariadb-server

# Install build prerequisites (requires root)
./storage/duckdb/build.sh -D

# Build, install and start MariaDB server
./storage/duckdb/build.sh -S

# Optional: build a DEB or RPM instead
./storage/duckdb/build.sh -p
```

On Rocky Linux 8, pass `-R` to use `gcc-toolset-12`:

```
./storage/duckdb/build.sh -R
```

Enabling the Plugin

The DuckDB plugin is not loaded by default. Add a configuration file to the server's drop-in directory:

- **Debian / Ubuntu:** `/etc/mysql/mariadb.conf.d/duckdb.cnf`
- **Rocky / Fedora / openSUSE:** `/etc/my.cnf.d/duckdb.cnf`

```
[mysqld]
plugin-maturity=alpha
plugin-load-add=ha_duckdb.so
duckdb-memory-limit=8G
```

Each line is significant:

- `plugin-maturity=alpha` is **required**. The server's default maturity threshold rejects alpha plugins; this line is the explicit opt-in.
- `plugin-load-add=ha_duckdb.so` loads the engine at startup.

- `duckdb-memory-limit` sets the cap on memory DuckDB itself may use. The default (1 GiB) is too low for most analytical workloads — raise it to reflect the host's available RAM.

Restart the server, then verify the engine is registered:

```
SHOW ENGINES\G
```

The output should include a `DuckDB` row with `Support: YES`.

Verifying the Install

```
CREATE DATABASE analytics;
USE analytics;

CREATE TABLE orders (
  id BIGINT PRIMARY KEY,
  amount DECIMAL(15, 2),
  created_at TIMESTAMP
) ENGINE=DuckDB DEFAULT CHARSET=utf8mb4;

INSERT INTO orders VALUES (1, 199.99, NOW()), (2, 299.50, NOW());

SELECT SUM(amount) FROM orders;
```

DuckDB requires UTF-8: specify `DEFAULT CHARSET=utf8mb4` (or another UTF-8 charset) on every DuckDB table. Non-UTF8 charsets fall back to binary comparison.

Supported Operations

- **DDL:** `CREATE TABLE`, `DROP TABLE`, `ALTER TABLE`, `RENAME TABLE`. `ALTER TABLE ... ENGINE=DuckDB` migrates an existing table into DuckDB storage.
- **`INSERT`:** all major MariaDB column types.
- **`SELECT`:** full pushdown to DuckDB, including aggregations, joins, window functions, `GROUP BY`, and `ORDER BY`.
- **`UPDATE` and `DELETE`:** translated to DuckDB SQL.
- **Cross-engine `JOIN`:** a single `SELECT` can join DuckDB tables with InnoDB (or other) tables. Example:

  ```
  SELECT d.id, d.amount, i.name
    FROM analytics.orders d        -- ENGINE=DuckDB
    JOIN inventory.products i      -- ENGINE=InnoDB
      ON d.product_id = i.id
   WHERE d.amount > 1000;
  ```

- **User-defined functions:** DuckDB-side UDFs are registered with MariaDB.

Configuration Variables

The plugin adds a family of `duckdb_*` server variables. The most commonly tuned ones:

Variable	Type	Default	Purpose
`duckdb_memory_limit`	integer (bytes)	`1073741824` (1 GiB)	Maximum memory DuckDB may use. Raise for analytical workloads.
`duckdb_max_threads`	integer	(auto)	Maximum DuckDB execution threads.
`duckdb_temp_directory`	string	(auto)	Directory used by DuckDB for spilling.
`duckdb_require_primary_key`	boolean	`ON`	Reject `CREATE TABLE` without a `PRIMARY KEY`.

Variable	Type	Default	Purpose
`duckdb_max_temp_directory_size`	integer (bytes)	(unlimited)	Cap on temp-directory usage.

Additional tuning and debugging variables (batching, log categories, optimizer hints, `EXPLAIN` verbosity, etc.) are exposed by the plugin. List the full current set with:

```
SHOW VARIABLES LIKE 'duckdb%';
```

Limitations

The engine is at alpha maturity. Known limitations at the time of writing:

- **No `AUTO_INCREMENT`** and no `UUID` default-value generation.
- **`DECIMAL` precision capped at 38** — DuckDB's maximum. Wider MariaDB `DECIMAL` columns fail at DDL conversion.
- **Strict `GROUP BY`** — DuckDB rejects `SELECT` columns that are neither in the `GROUP BY` clause nor aggregated, even when MariaDB's `sql_mode` would allow it.
- **No XA `PREPARE`.**
- **UTF-8 only** — non-UTF8 charsets fall back to binary comparison. UCA-based MariaDB collations are approximated using DuckDB's `NOCASE` / `NOACCENT` collations.
- **Some MariaDB functions are not pushdown-compatible** — for example, `GROUP_CONCAT()`, `DATE_FORMAT()`, `JSON_CONTAINS()`, `FOUND_ROWS()`, and `LAST_INSERT_ID()` have no DuckDB equivalent or differ in syntax. Such queries fall back to MariaDB-side evaluation.
- **`ALTER COLUMN DROP DEFAULT`** isn't propagated to the DuckDB catalog.
- **`TIMESTAMP` is stored as `TIMESTAMPTZ`** — keep MariaDB and DuckDB timezone settings consistent to avoid value shifts.
- **Cross-engine scan is single-threaded** — only the DuckDB side of a cross-engine query is parallelized.
- **Cross-engine `INSERT` (DuckDB → InnoDB)** has restrictions; see the engine compatibility matrix.

A maintained compatibility matrix is published in the server repository at `storage/duckdb/docs/mariadb-duckdb-incompatibilities.md`.

FederatedX

> **Warning:**
>
> This storage engine has been deprecated.

See About FederatedX.

An introduction to the FederatedX storage engine, a fork of MySQL's Federated engine, allowing access to remote tables as if they were local. This storage engine has been deprecated.

See Differences Between FederatedX and Federated.

This page outlines the key enhancements in FederatedX over the original Federated engine, including support for transactions and a refactored codebase. This storage engine has been deprecated.

This page is licensed: CC BY-SA / Gnu FDL

About FederatedX

> **Warning:**
>
> This storage engine has been deprecated.

The FederatedX storage engine is a fork of MySQL's Federated storage engine, which is no longer being developed by Oracle. The original purpose of FederatedX was to keep this storage engine's development progressing– to both add new features as well as fix old bugs.

Since MariaDB 10.0, the CONNECT storage engine also allows access to a remote database via MySQL or ODBC connection (table types: MYSQL, ODBC). However, in the current implementation there are several limitations.

What is the FederatedX storage engine?

The FederatedX Storage Engine is a storage engine that works with both MariaDB and MySQL. Where other storage engines are built as interfaces to lower-level file-based data stores, FederatedX uses libmysql to talk to the data source, the data source being a remote RDBMS. Currently, since FederatedX only uses libmysql, it can only talk to another MariaDB or MySQL RDBMS. The plan is of course to be able to use other RDBMS systems as a data source. There is an existing project Federated ODBC which was able to use PostgreSQL as a remote data source, and it is this type of functionality which are brought to FederatedX in subsequent versions.

History

The history of FederatedX is derived from the History of Federated. Cisco needed a MySQL storage engine that would allow them to consolidate remote tables on some sort of routing device, being able to interact with these remote tables as if they were local to the device, but not actually on the device, since the routing device had only so much storage space. The first prototype of the Federated Storage Engine was developed by JD (need to check on this- Brian Aker can verify) using the HANDLER interface. Brian handed the code to Patrick Galbraith and explained how it needed to work, and with Brian and Monty's tutelage and Patrick had a working Federated Storage Engine with MySQL 5.0. Eventually, Federated was released to the public in a MySQL 5.0 release.

When MySQL 5.1 became the production release of MySQL, Federated had more features and enhancements added to it, namely:

- New Federated SERVER added to the parser. This was something Cisco needed that made it possible to change the connection parameters for numerous Federated tables at once without having to alter or re-create the Federated tables.
- Basic Transactional support– for supporting remote transactional tables
- Various bugs that needed to be fixed from MySQL 5.0
- Plugin capability

In MariaDB 10.0.2 FederatedX got support for assisted table discovery.

Installing the Plugin

Although the plugin's shared library is distributed with MariaDB by default, the plugin is not actually installed by MariaDB by default. There are two methods that can be used to install the plugin with MariaDB.

The first method can be used to install the plugin without restarting the server. You can install the plugin dynamically by executing INSTALL SONAME or INSTALL PLUGIN:

```
INSTALL SONAME 'ha_federatedx';
```

The second method can be used to tell the server to load the plugin when it starts up. The plugin can be installed this way by providing the –plugin-load or the –plugin-load-add options. This can be specified as a command-line argument to mariadbd or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
plugin_load_add = ha_federatedx
```

Uninstalling the Plugin

You can uninstall the plugin dynamically by executing UNINSTALL SONAME or UNINSTALL PLUGIN:

```
UNINSTALL SONAME 'ha_federatedx';
```

If you installed the plugin by providing the –plugin-load or the –plugin-load-add options in a relevant server option group in an option file, then those options should be removed to prevent the plugin from being loaded the next time the server is restarted.

How FederatedX works

Every storage engine has to implement derived standard handler class API methods for a storage engine to work. FederatedX is no different in that regard. The big difference is that FederatedX needs to implement these handler methods in such as to construct SQL statements to run on the remote server and if there is a result set, process that result set into the internal handler format so that the result is returned to the user.

Internal workings of FederatedX

Normal database files are local and as such: You create a table called
'users', a file such as 'users.MYD' is created. A handler reads, inserts, deletes, updates data in this file. The data is stored in particular format, so to read, that data has to be parsed into fields, to write, fields have to be stored in this format to write to this data file.

With the FederatedX storage engine, there are no local files for each table's data (such as .MYD). A foreign database will store the data that would normally be in this file. This will necessitate the use of MySQL client API to read, delete, update, insert this data. The data will have to be retrieve via an SQL call
"`SELECT * FROM users`". Then, to read this data, it will have to be retrieved via `mysql_fetch_row` one row at a time, then converted from the column in this select into the format that the handler expects.

The basic functionality of how FederatedX works is:

- The user issues an SQL statement against the local federatedX table. This statement is parsed into an item tree
- FederatedX uses the mysql handler API to implement the various methods required for a storage engine. It has access to the item tree for the SQL statement issued, as well as the Table object and each of its Field members. At
- With this information, FederatedX constructs an SQL statement
- The constructed SQL statement is sent to the Foreign data source through libmysql using the mysql client API

- The foreign database reads the SQL statement and sends the result back through the mysql client API to the origin
- If the original SQL statement has a result set from the foreign data source, the FederatedX storage engine iterates through the result set and converts each row and column to the internal handler format
- If the original SQL statement only returns the number of rows returned (affected_rows), that number is added to the table stats which results in the user seeing how many rows were affected.

FederatedX table creation

The create table will simply create the .frm file, and within the `CREATE TABLE` SQL statement, there SHALL be any of the following :

```
connection=scheme://username:password@hostname:port/database/tablename
connection=scheme://username@hostname/database/tablename
connection=scheme://username:password@hostname/database/tablename
connection=scheme://username:password@hostname/database/tablename
```

Or using the syntax introduced in MySQL versions 5.1 for a Federated server (SQL/MED Spec xxxx)

```
connection="connection_one"
connection="connection_one/table_foo"
```

An example of a connect string specifying all the connection parameters would be:

```
connection=mysql://username:password@hostname:port/database/tablename
```

Or, using a Federated server, first a server is created:

```
CREATE SERVER 'server_one' FOREIGN DATA WRAPPER 'mysql' OPTIONS
  (HOST '127.0.0.1',
  DATABASE 'db1',
  USER 'root',
  PASSWORD '',
  PORT 3306,
  SOCKET '',
  OWNER 'root');
```

MariaDB starting with 10.11.12

You can also use ‘mariadb’ as a wrapper.

Then the FederatedX table is created specifying the newly created Federated server.
The following statements creates a federated table, `federated.t1` against the table `db1.t1` on the remote server.

```
CREATE TABLE federated.t1 (
  `id` INT(20) NOT NULL,
  `name` VARCHAR(64) NOT NULL DEFAULT ''
  )
ENGINE="FEDERATED" DEFAULT CHARSET=latin1
CONNECTION='server_one';
```

(Note that in MariaDB, the original Federated storage engine is replaced with the new FederatedX storage engine. And for backward compatibility, the old name “FEDERATED” is used in create table. So in MariaDB, the engine type should be given as “FEDERATED” without an extra “X”, not “FEDERATEDX”).

The equivalent of above, if done specifying all the connection parameters

```
CONNECTION="mysql://root@127.0.0.1:3306/db1/t1"
```

You can also change the server to point to a new schema:

```
ALTER SERVER 'server_one' OPTIONS(DATABASE 'db2');
```

All subsequent calls to any FederatedX table using the ‘server_one’ will now be against tables in `db2`! Guess what? You no longer have to perform an alter table in order to point one or more FederatedX tables to a new server!

This `connection="connection string"` is necessary for the handler to be able to connect to the foreign server, either by URL, or by server name.

Method calls

One way to see how the FederatedX storage engine works is to compile a debug build of MariaDB and turn on a trace log. Using a two column table, with one record, the following SQL statements shown below, can be analyzed for what internal methods they result in being called.

SELECT

If the query is for instance “`SELECT * FROM foo`”, then the primary methods you would see with debug turned on would be first:

```
ha_federatedx::info
ha_federatedx::scan_time:
ha_federatedx::rnd_init: share->select_query SELECT * FROM foo
ha_federatedx::extra
```

Then for every row of data retrieved from the foreign database in the result set:

```
ha_federatedx::rnd_next
ha_federatedx::convert_row_to_internal_format
ha_federatedx::rnd_next
```

After all the rows of data that were retrieved, you would see:

```
ha_federatedx::rnd_end
ha_federatedx::extra
ha_federatedx::reset
```

INSERT

If the query was “`INSERT INTO foo (id, ts) VALUES (2, now());`”, the trace would be:

```
ha_federatedx::write_row
ha_federatedx::reset
```

UPDATE

If the query was “`UPDATE foo SET ts = now() WHERE id = 1;`”, the resultant trace would be:

```
ha_federatedx::index_init
ha_federatedx::index_read
ha_federatedx::index_read_idx
ha_federatedx::rnd_next
ha_federatedx::convert_row_to_internal_format
ha_federatedx::update_row

ha_federatedx::extra
ha_federatedx::extra
ha_federatedx::extra
ha_federatedx::external_lock
ha_federatedx::reset
```

FederatedX capabilities and limitations

- Tables MUST be created on the foreign server prior to any action on those tables via the handler, first version. IMPORTANT: IF you MUST use the FederatedX storage engine type on the REMOTE end, make sure that the table you connect to IS NOT a table pointing BACK to your ORIGINAL table! You know and have heard the screeching of audio feedback? You know putting two mirrors in front of each other how the reflection continues for eternity? Well, need I say more?!
- There is no way for the handler to know if the foreign database or table has changed. The reason for this is that this database has to work like a data file that would never be written to by anything other than the database. The integrity of the data in the local table could be breached if there was any change to the foreign database.
- Support for SELECT, INSERT, UPDATE, DELETE indexes.
- No ALTER TABLE, DROP TABLE or any other Data Definition Language calls.
- Prepared statements will not be used in the first implementation, it remains to be seen whether the limited subset of the client API for the server supports this.
- This uses SELECT, INSERT, UPDATE, DELETE and not HANDLER for its implementation.
- This will not work with the query cache.
- FederatedX does not support GEOMETRY types. Such tables cannot be created explicitly, nor discovered.

How do you use FederatedX?

To use this handler, it's very simple. You must have two databases running, either both on the same host, or on different hosts.

First, on the foreign database you create a table, for example:

```
CREATE TABLE federated.test_table (
  id     INT(20) NOT NULL AUTO_INCREMENT,
  name   VARCHAR(32) NOT NULL DEFAULT '',
  other  INT(20) NOT NULL DEFAULT '0',
  PRIMARY KEY  (id),
  KEY name (name),
  KEY other_key (other))
DEFAULT CHARSET=latin1;
```

Then, on the server that are connecting to the foreign host (client), you create a federated table without specifying the table structure:

```
CREATE TABLE federated_test_table ENGINE=FEDERATED
  CONNECTION='mysql://root@127.0.0.1:9306/federated/test_table';
```

Notice the "ENGINE" and "CONNECTION" fields? This is where you respectively set the engine type, "FEDERATED" and foreign host information, this being the database your 'client' database will connect to and use as the "data file". Obviously, the foreign database is running on port 9306, so you want to start up your other

database so that it is indeed on port 9306, and your FederatedX database on a port other than that. In my setup, I use port 5554 for FederatedX, and port 5555 for the foreign database.

Alternatively (or if you're using MariaDB before version 10.0.2) you specify the federated table structure explicitly:

```
CREATE TABLE federated_test_table (
  id     INT(20) NOT NULL AUTO_INCREMENT,
  name   VARCHAR(32) NOT NULL DEFAULT '',
  other  INT(20) NOT NULL DEFAULT '0',
  PRIMARY KEY  (id),
  KEY name (name),
  KEY other_key (other))
ENGINE=FEDERATED
DEFAULT CHARSET=latin1
CONNECTION='mysql://root@127.0.0.1:9306/federated/test_table';
```

In this case the table structure must match exactly the table on the foreign server.

How to see the storage engine in action

When developing this handler, I compiled the FederatedX database with debugging:

```
./configure --with-federatedx-storage-engine \
  --prefix=/home/mysql/mysql-build/federatedx/ --with-debug
```

Once compiled, I did a 'make install' (not for the purpose of installing the binary, but to install all the files the binary expects to see in the directory I specified in the build with

```
--prefix=/home/code-dev/maria
```

Then, I started the foreign server:

```
/usr/local/mysql/bin/mysqld_safe \
  --user=mysql --log=/tmp/mysqld.5555.log -P 5555
```

Then, I went back to the directory containing the newly compiled mysqld `<builddir>/sql/`, started up gdb:

```
gdb ./mysqld
```

Then, within the (gdb) prompt:

```
(gdb) run --gdb --port=5554 --socket=/tmp/mysqld.5554 --skip-innodb --debug
```

Next, I open several windows for each:

1. Tail the debug trace: tail -f /tmp/mysqld.trace|grep ha_fed
2. Tail the SQL calls to the foreign database: tail -f /tmp/mysqld.5555.log
3. A window with a client open to the federatedx server on port 5554
4. A window with a client open to the federatedx server on port 5555

I would create a table on the client to the foreign server on port 5555, and then to the FederatedX server on port 5554. At this point, I would run whatever queries I wanted to on the FederatedX server, just always remembering that whatever changes I wanted to make on the table, or if I created new tables, that I would have to do that on the foreign server.

Another thing to look for is 'show variables' to show you that you have support for FederatedX handler support:

```
SHOW VARIABLES LIKE '%federat%';
```

and:

```
SHOW storage engines;
```

Both should display the federatedx storage handler.

How do I create a federated server?

A federated server is a way to have a foreign data source defined– with all connection parameters– so that you don't have to specify explicitly the connection parameters in a string.

For instance, if you wanted to connect to a table, `first_db.test_table`, using this definition:

```
CREATE TABLE federated_test_table ENGINE=FEDERATED
  CONNECTION='mysql://patg@192.168.1.123/first_db/test_table';
```

You could instead create this with a server:

```
CREATE SERVER 'server_one' FOREIGN DATA WRAPPER 'mysql' OPTIONS
  (HOST '192.168.1.123',
  DATABASE 'first_db',
  USER 'patg',
  PASSWORD '',
  PORT 3306,
  SOCKET '',
  OWNER 'root');
```

You could now specify the server instead of the full URL in the connection string:

```
CREATE TABLE federated_test_table ENGINE=FEDERATED
  CONNECTION='server_one/test_table';
```

On the server where you create this `federated_test_table` you will now have access to the table `test_table` in the `first_db` database on the remote server found on 192.168.1.123.

How does FederatedX differ from the old Federated Engine?

FederatedX from a user point of view is the same for the most part. What is different with FederatedX and Federated is the following:

- Rewrite of the main Federated source code from one single ha_federated.cc file into three main abstracted components:
  - ha_federatedx.cc - Core implementation of FederatedX
  - federated_io.cc - Parent connection class to be over-ridden by derived classes for each RDBMS/client lib
  - federatated_io_.cc - derived federated_io class for a given RDBMS
  - federated_txn.cc - New support for using transactional engines on the foreign server using a connection poll
- Various bugs fixed (need to look at opened bugs for Federated)

Where can I get FederatedX

FederatedX is part of MariaDB 5.1 and later. MariaDB merged with the latest FederatedX when there is a need to get a bug fixed. You can get the latest code/follow/participate in the project from the FederatedX home page.

What are the plans for FederatedX?

- Support for other RDBMS vendors using ODBC
- Support for pushdown conditions
- Ability to limit result set sizes

Differences Between FederatedX and Federated

> **Warning:**
>
> This storage engine has been deprecated.

The main differences are:

New features in FederatedX

- Transactions (beta feature)
- Supports partitions (alpha feature)
- New class structure which allows developers to write connection classes for other RDBMSs without having to modify base classes for FederatedX

Different behavior

- FederatedX is statically compiled into MariaDB by default.
- When you create a table with FederatedX, the connection are tested. The `CREATE` will fail if MariaDB can't connect to the remote host or if the remote table doesn't exist.

InnoDB Introduction

Overview

MariaDB Enterprise Server uses the InnoDB storage engine by default. InnoDB is a general purpose transactional storage engine that is performant, ACID-compliant, and well-suited for most workloads.

Benefits

The InnoDB storage engine:

- Is available with all versions of MariaDB Enterprise Server and MariaDB Community Server.
- Is a general purpose storage engine.
- Is transactional and well-suited for online transactional processing (OLTP) workloads.

- Is ACID-compliant.
- Performs well for mixed read-write workloads.
- Supports online DDL.

Feature Summary

Feature	Detail	Resources
Storage Engine	InnoDB	
Availability	All ES and CS versions	MariaDB Enterprise Server
Workload Optimization	Transactional	
Table Orientation	Row	
Default Row Format	Dynamic	InnoDB Row Formats InnoDB Dynamic Row Format
ACID-compliant	Yes	
XA Transactions	Yes	
Primary Keys	Yes	InnoDB Primary Keys
Auto-Increment	Yes	InnoDB AUTO_INCREMENT Columns
Sequences	Yes	InnoDB Sequences
Foreign Keys	Yes	InnoDB Foreign Keys
Indexes	Yes	InnoDB Indexes
Secondary Indexes	Yes	InnoDB Secondary Indexes
Unique Indexes	Yes	InnoDB Unique Indexes
Full-text Search	Yes	InnoDB Full-text Indexes
Spatial Indexes	Yes	InnoDB Spatial Indexes
Compression	Yes	Configure InnoDB Page Compression
Data-at-Rest Encryption	Yes	
High Availability (HA)	Yes	• MariaDB Replication • Galera Cluster
Main Memory Caching	Yes	InnoDB Buffer Pool
Transaction Logging	Yes	• InnoDB Redo Log (Crash Safety) • InnoDB Undo Log (MVCC)
Garbage Collection	Yes	InnoDB Purge Threads
Online Schema changes	Yes	InnoDB Schema Changes
Non-locking Reads	Yes	
Row Locking	Yes	

Examples

Creating an InnoDB Table

```
CREATE DATABASE hq_sales;
```

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
) ENGINE = InnoDB;
```

```
SELECT TABLE_SCHEMA, TABLE_NAME, ENGINE
FROM information_schema.TABLES
WHERE TABLE_SCHEMA='hq_sales'
AND TABLE_NAME='invoices';
+--------------+------------+--------+
| TABLE_SCHEMA | TABLE_NAME | ENGINE |
+--------------+------------+--------+
| hq_sales     | invoices   | InnoDB |
+--------------+------------+--------+
```

InnoDB File Format

Setting a Table's File Format

A table's tablespace is tagged with the lowest InnoDB file format that supports the table's row format. So, even if the `Barracuda` file format is enabled, tables that use the `COMPACT` or `REDUNDANT` row formats are tagged with the `Antelope` file format in the information_schema.INNODB_SYS_TABLES table.

Supported File Formats

The InnoDB storage engine supports two different file formats:

- `Antelope`
- `Barracuda`

Antelope

In MariaDB 10.2.1 and before, the default file format is `Antelope`. In MariaDB 10.2.2 and later, the `Antelope` file format is deprecated.

`Antelope` is the original InnoDB file format. It supports the `COMPACT` and `REDUNDANT` row formats, but not the `DYNAMIC` or `COMPRESSED` row formats.

Barracuda

In MariaDB 10.1 and before, the `Barracuda` file format is only supported if the innodb_file_per_table system variable is set to `ON`. In MariaDB 10.2.2 and later, the default file format is `Barracuda` and `Antelope` is deprecated.

`Barracuda` is a newer InnoDB file format. It supports the `COMPACT`, `REDUNDANT`, `DYNAMIC` and `COMPRESSED` row formats. Tables with large BLOB or TEXT columns in particular could benefit from the dynamic row format.

Future Formats

InnoDB might use new file formats in the future. Each format will have an identifier from 0 to 25, and a name. The names have already been decided, and are animal names listed in an alphabetical order: Antelope, Barracuda, Cheetah, Dragon, Elk, Fox, Gazelle, Hornet, Impala, Jaguar, Kangaroo, Leopard, Moose, Nautilus, Ocelot, Porpoise, Quail, Rabbit, Shark, Tiger, Urchin, Viper, Whale, Xenops, Yak and Zebra.

Checking a Table's File Format.

The information_schema.INNODB_SYS_TABLES table can be queried to see the file format used by a table.

A table's tablespace is tagged with the lowest InnoDB file format that supports the table's row format. So, even if the `Barracuda` file format is enabled, tables that use the `COMPACT` or `REDUNDANT` row formats are tagged with the `Antelope` file format in the information_schema.INNODB_SYS_TABLES table.

Compatibility

Each tablespace is tagged with the id of the most recent file format used by one of its tables. All versions of InnoDB can read tables that use an older file format. However, it can not read from more recent formats. For this reason, each time InnoDB opens a table it checks the tablespace's format, and returns an error if a newer format is used.

This check can be skipped via the innodb_file_format_check variable. Beware that, is InnoDB tries to repair a table in an unknown format, the table are corrupted! This happens on restart if innodb_file_format_check is disabled and the server crashed, or it was closed with fast shutdown.

To downgrade a table from the Barracuda format to Antelope, the table's `ROW_FORMAT` can be set to a value supported by Antelope, via an ALTER TABLE statement. This recreates the indexes.

The Antelope format can be used to make sure that tables work on MariaDB and MySQL servers which are older than 5.5.

InnoDB Limitations

The InnoDB storage engine has the following limitations.

Limitations on Schema

- InnoDB tables can have a maximum of 1,017 columns. This includes virtual generated columns.
- InnoDB tables can have a maximum of 64 secondary indexes.
- A multicolumn index on InnoDB can use a maximum of 32 columns. If you attempt to create a multicolumn index that uses more than 32 columns, MariaDB returns an Error 1070.

Limitations on Size

- With the exception of variable-length columns (that is, VARBINARY, VARCHAR, BLOB and TEXT), rows in InnoDB have a maximum length of roughly half the page size for 4KB, 8KB, 16KB and 32KB page sizes.
- The maximum size for BLOB and TEXT columns is 4GB. This also applies to LONGBLOB and LONGTEXT.
- MariaDB imposes a row-size limit of 65,535 bytes for the combined sizes of all columns. If the table contains BLOB or TEXT columns, these only count for 9 - 12 bytes in this calculation, given that their content is stored separately.
- 32-bit operating systems have a maximum file size limit of 2GB. When working with large tables using this architecture, configure InnoDB to use smaller data files.
- The maximum size for the combined InnoDB log files is 512GB.
- With tablespaces, the minimum size is 10MB, the maximum varies depending on the InnoDB Page Size.

InnoDB Page Size	Maximum Tablespace Size
4KB	16TB
8KB	32TB
16KB	64TB
32KB	128TB
64KB	256TB

Page Sizes

Using the innodb_page_size system variable, you can configure the size in bytes for InnoDB pages. Pages default to 16KB. There are certain limitations on how you use this variable.

- MariaDB instances using one page size cannot use data files or log files from an instance using a different page size.
- When using a Page Size of 4KB or 8KB, the maximum index key length is lowered proportionately.

InnoDB Page Size	Index Key Length
4KB	768B
8KB	1536B
16KB	3072B

Limitations on Tables

InnoDB has the following table-specific limitations.

- When you issue a DELETE statement, InnoDB doesn't regenerate the table, rather it deletes each row from the table one by one.
- When running MariaDB on Windows, InnoDB stores databases and tables in lowercase. When moving databases and tables in a binary format from Windows to a Unix-like system or from a Unix system to Windows,

you need to rename these to use lowercase.
- When using cascading foreign keys, operations in the cascade don't activate triggers.

Table Analysis

When running ANALYZE TABLE twice on a table in which statements or transactions are running, MariaDB blocks the second ANALYZE TABLE until the statement or transaction is complete. This occurs because the statement or transaction blocks the second ANALYZE TABLE statement from reloading the table definition, which it must do since the old one was marked as obsolete after the first statement.

Table Status

SHOW TABLE STATUS statements do not provide accurate statistics for InnoDB, except for the physical table size.

The InnoDB storage engine does not maintain internal row counts. Transactions isolate writes, which means that concurrent transactions will not have the same row counts.

Auto-incrementing Columns

- When defining an index on an auto-incrementing column, it must be defined in a way that allows the equivalent of `SELECT MAX(col)` lookups on the table.
- Restarting MariaDB may cause InnoDB to reuse old auto-increment values, such as in the case of a transaction that was rolled back.
- When auto-incrementing columns run out of values, INSERT statements generate duplicate-key errors.

Transactions and Locks

- You can modify data on a maximum of 96 * 1023 concurrent transactions that generate undo records.
- Of the 128 rollback segments, InnoDB assigns 32 to non-redo logs for transactions that modify temporary tables and related objects, reducing the maximum number of concurrent data-modifying transactions to 96,000, from 128.000.
- The limit is 32,000 concurrent transactions when all data-modifying transactions also modify temporary tables.
- Issuing a LOCK TABLES statement sets two locks on each table when the innodb_table_locks system variable is enabled (the default).
- When you commit or roll back a transaction, any locks set in the transaction are released. You don't need to issue LOCK TABLES statements when the autocommit variable is enabled, as InnoDB would immediately release the table locks.

This page is licensed: CC BY-SA / Gnu FDL

AUTO_INCREMENT Handling in InnoDB

AUTO_INCREMENT Lock Modes

The innodb_autoinc_lock_mode system variable determines the lock mode when generating AUTO_INCREMENT values for InnoDB tables. These modes allow InnoDB to make significant performance optimizations in certain circumstances.

The innodb_autoinc_lock_mode system variable may be removed in a future release. See MDEV-19577 for more information.

Traditional Lock Mode

When innodb_autoinc_lock_mode is set to `0`, InnoDB uses the traditional lock mode.

In this mode, InnoDB holds a table-level lock for all INSERT statements until the statement completes.

Consecutive Lock Mode

When innodb_autoinc_lock_mode is set to `1`, InnoDB uses the consecutive lock mode.

In this mode, InnoDB holds a table-level lock for all bulk INSERT statements (such as LOAD DATA or INSERT … SELECT) until the end of the statement. For simple INSERT statements, no table-level lock is held. Instead, a lightweight mutex is used which scales significantly better. This is the default setting.

Interleaved Lock Mode

When innodb_autoinc_lock_mode is set to `2`, InnoDB uses the interleaved lock mode.

In this mode, InnoDB does not hold any table-level locks at all. This is the fastest and most scalable mode, but is not safe for statement-based replication.

Setting AUTO_INCREMENT Values

The AUTO_INCREMENT value for an InnoDB table can be set for a table by executing the ALTER TABLE statement and specifying the AUTO_INCREMENT table option:

```
ALTER TABLE tab AUTO_INCREMENT=100;
```

However, in MariaDB 10.2.3 and before, InnoDB stores the table's AUTO_INCREMENT counter in memory. In these versions, when the server restarts, the counter is re-initialized to the highest value found in the table. This means that the above operation can be undone if the server is restarted before any rows are written to the table.

In MariaDB 10.2.4 and later, the AUTO_INCREMENT counter is persistent, so this restriction is no longer present. Persistent, however, does not mean transactional. Gaps may still occur in some cases, such as if a INSERT IGNORE statement fails, or if a user executes ROLLBACK or ROLLBACK TO SAVEPOINT.

For example:

```
CREATE TABLE t1 (pk INT AUTO_INCREMENT PRIMARY KEY, i INT, UNIQUE (i)) ENGINE=InnoDB;

INSERT INTO t1 (i) VALUES (1),(2),(3);
INSERT IGNORE INTO t1 (pk, i) VALUES (100,1);
Query OK, 0 rows affected, 1 warning (0.099 sec)

SELECT * FROM t1;
+----+------+
| pk | i    |
+----+------+
|  1 |    1 |
|  2 |    2 |
|  3 |    3 |
+----+------+

SHOW CREATE TABLE t1\G
*************************** 1. row ***************************
       Table: t1
Create Table: CREATE TABLE `t1` (
  `pk` int(11) NOT NULL AUTO_INCREMENT,
  `i` int(11) DEFAULT NULL,
  PRIMARY KEY (`pk`),
  UNIQUE KEY `i` (`i`)
) ENGINE=InnoDB AUTO_INCREMENT=4 DEFAULT CHARSET=latin1
```

If the server is restarted at this point, then the AUTO_INCREMENT counter will revert to `101`, which is the persistent value set as part of the failed INSERT IGNORE.

```
# Restart server
SHOW CREATE TABLE t1\G
*************************** 1. row ***************************
       Table: t1
Create Table: CREATE TABLE `t1` (
  `pk` int(11) NOT NULL AUTO_INCREMENT,
  `i` int(11) DEFAULT NULL,
  PRIMARY KEY (`pk`),
  UNIQUE KEY `i` (`i`)
) ENGINE=InnoDB AUTO_INCREMENT=101 DEFAULT CHARSET=latin1
```

Binary Log Group Commit and InnoDB Flushing Performance

Overview

When both innodb_flush_log_at_trx_commit=1 (the default) is set and the binary log is enabled, there is now one less sync to disk inside InnoDB during commit (2 syncs shared between a group of transactions instead of 3).

Durability of commits is not decreased — this is because even if the server crashes before the commit is written to disk by InnoDB, it are recovered from the binary log at next server startup (and it is guaranteed that sufficient information is synced to disk so that such a recovery is always possible).

Switching to Old Flushing Behavior

The old behavior, with 3 syncs to disk per (group) commit (and consequently lower performance), can be selected with the new innodb_flush_log_at_trx_commit=3 option. There is normally no benefit to doing this, however there are a couple of edge cases to be aware of.

Non-durable Binary Log Settings

If innodb_flush_log_at_trx_commit=1 is set and the binary log is enabled, but sync_binlog=0 is set, then commits are not guaranteed durable inside InnoDB after commit. This is because if sync_binlog=0 is set and if the server crashes, then transactions that were not flushed to the binary log prior to the crash are missing from the binary log.

In this specific scenario, innodb_flush_log_at_trx_commit=3 can be set to ensure that transactions are durable in InnoDB, even if they are not necessarily durable from the perspective of the binary log.

One should be aware that if sync_binlog=0 is set, then a crash is nevertheless likely to cause transactions to be missing from the binary log. This will cause the binary log and InnoDB to be inconsistent with each other. This is also likely to cause any replication slaves to become inconsistent, since transactions are replicated through the binary log. Thus it is recommended to set sync_binlog=1. With the group commit improvements introduced in MariaDB 5.3, this setting has much less penalty in recent versions compared to older versions of MariaDB and MySQL.

Recent Transactions Missing from Backups

mariadb-backup and Percona XtraBackup only see transactions that have been flushed to the redo log. With the group commit improvements, there may be a small delay (defined by the binlog_commit_wait_usec system variable) between when a commit happens and when the commit are included in a backup.

Note that the backup will still be fully consistent with itself and the binary log. This problem is normally not an issue in practice. A backup usually takes a long time to complete (relative to the 1 second or so that binlog_commit_wait_usec is normally set to), and a backup usually includes a lot of transactions that were committed during the backup. With this in mind, it is not generally noticeable if the backup does not include transactions that were committed during the last 1 second or so of the backup process. It is just mentioned here for completeness.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Asynchronous I/O

From MariaDB 10.5, InnoDB uses asynchronous I/O to read from and write to disk asynchronously. This forms part of the InnoDB Background Thread Pool.

Stages

Each asynchronous IO operation goes through multiple stages:

1. SUBMITTED – The IO operation is initiated.

- For asynchronous writes, this typically occurs in the buffer pool flushing code.
- For asynchronous reads, this may happen during buffer pool loading at startup or in prefetching logic.

1. COMPLETED_IN_OS – The operating system notifies InnoDB that the I/O operation is complete.

- If using libaio or io_uring, a dedicated thread handles this notification.
- The completed IO operation is then submitted to InnoDB's internal thread pool (tpool).

1. EXECUTING_COMPLETION_TASK – A tpool thread processes the completion task for the IO operation.
2. COMPLETED – The IO operation is fully handled.

Resource Constraints and Queuing Mechanisms

Waiting for IO Slots

The total number of pending asynchronous IO operations is limited by:

```
total_count = number_of_IO_threads * 256
```

where number_of_IO_threads refers to either innodb_io_read_threads or innodb_io_write_threads.

Each IO operation is associated with an IO slot, which contains necessary metadata such as the file handle, operation type, offset, length, and any OS error codes. Initially, all total_count slots are free, but as pending IO requests accumulate, slots get occupied. If all slots are in use, additional IO requests must wait for a free slot.

Queuing Mechanism

The number of completion tasks (EXECUTING_COMPLETION_TASK stage) that can run in parallel is also limited by innodb_io_read_threads or innodb_io_write_threads. If too many IO operations complete simultaneously, they cannot all be processed in parallel and must be queued, respecting the thread limit.

Variables

From MariaDB 11.5, a number of status variables were added to give insight into the above operations:

- innodb_async_reads_pending – Number of read IO operations currently in progress (from SUBMITTED to COMPLETED).

- innodb_async_reads_tasks_running – Number of read IO operations currently in the EXECUTING_COMPLETION_TASK state.
- innodb_async_reads_total_count – Total number of read completion tasks that have finished execution.
- innodb_async_reads_queue_size – Current size of the queue (see Queuing Mechanism).
- innodb_async_reads_wait_slot_sec – Total wait time for a free IO slot (see Waiting for IO Slots).
- innodb_async_reads_total_enqueues – Total number of read operations that were queued (see Queuing Mechanism). Includes those still waiting and making up `innodb_async_reads_queue_size`.

Similar variables exist for write operations:

- innodb_async_writes_pending
- innodb_async_writes_tasks_running
- innodb_async_reads_total_count
- innodb_async_writes_queue_size
- innodb_async_writes_wait_slot_sec
- innodb_async_writes_total_enqueues

InnoDB Buffer Pool

The InnoDB storage engine in MariaDB Enterprise Server utilizes the Buffer Pool as a crucial in-memory cache. This Buffer Pool stores recently accessed data pages, enabling faster retrieval for subsequent requests. Recognizing patterns of access, InnoDB also employs predictive prefetching, caching nearby pages when sequential access is detected. To manage memory efficiently, a least recently used (LRU) algorithm is used to evict older, less frequently accessed pages.

To optimize server restarts, the Buffer Pool's contents can be preserved across shutdowns. At shutdown, the page numbers of all pages residing in the Buffer Pool are recorded. Upon the next startup, InnoDB reads this dump of page numbers and reloads the corresponding data pages from their respective data files, effectively avoiding a "cold" cache scenario.

The size of each individual page within the Buffer Pool is determined by the setting of the innodb_page_size system variable.

How the Buffer Pool Works

The buffer pool attempts to keep frequently-used blocks in the buffer, and so essentially works as two sublists, a *new* sublist of recently-used information, and an *old* sublist of older information. By default, 37% of the list is reserved for the old list.

When new information is accessed that doesn't appear in the list, it is placed at the top of the old list, the oldest item in the old list is removed, and everything else bumps back one position in the list.

When information is accessed that appears in the *old* list, it is moved to the top the new list, and everything above moves back one position.

innodb_buffer_pool_size

The most important server system variable is innodb_buffer_pool_size. This size should contain most of the active data set of your server so that SQL request can work directly with information in the buffer pool cache. Starting at several gigabytes of memory is a good starting point if you have that RAM available. Once warmed up to its normal load there should be very few innodb_buffer_pool_reads compared to innodb_buffer_pool_read_requests. Look how these values change over a minute. If the change in innodb_buffer_pool_reads is less than 1% of the change in innodb_buffer_pool_read_requests then you have a good amount of usage. If you are getting the status variable

innodb_buffer_pool_wait_free increasing then you don't have enough buffer pool (or your flushing isn't occurring frequently enough).

The larger the size, the longer it takes to initialize.

> **Note:**
>
> Make sure that the size is not too large, because this can cause swapping, which more than undoes the benefits of a large buffer pool.

> **Warning:**
>
> **Using ColumnStore?**
>
> The standard recommendation to use a large portion of your RAM for the InnoDB buffer pool does not apply if you are also running MariaDB ColumnStore on the same server. ColumnStore reserves 75% of system RAM by default. Over-allocating the InnoDB buffer pool in a combined environment will likely trigger the Linux OOM killer.
>
> Please refer to the ColumnStore Memory Requirements for accurate sizing and validation instructions.

The buffer pool can be set dynamically. See Setting Innodb Buffer Pool Size Dynamically.

Buffer Pool Changes

> **Warning:**
>
> From MariaDB 10.11.12 / 11.4.6 / 11.8.2, there are significant changes to the InnoDB buffer pool behavior.

MariaDB server deprecates and ignores the `innodb_buffer_pool_chunk_size`. Now, the buffer pool size is changed in arbitrary 1-megabyte increments, all the way up to `innodb_buffer_pool_size_max`, which must be specified at startup.

If `innodb_buffer_pool_size_max` is `0` or not specified, it defaults to the `innodb_buffer_pool_size` value.

The `innodb_buffer_pool_size_auto_min` variable specifies the minimum size the buffer pool can be shrunk to by a memory pressure event. When a memory pressure event occurs, MariaDB server attempts to shrink `innodb_buffer_pool_size` halfway between its current value and the `innodb_buffer_pool_size_auto_min` value. If `innodb_buffer_pool_size_auto_min` is not specified or `0`, its default value is adjusted to `innodb_buffer_pool_size` — in other words, memory pressure events are disregarded by default.

The minimum `innodb_buffer_pool_size` is 320 pages (256*5/4). With the default value of `innodb_page_size=16k`, this corresponds to 5 MiB. However, since `innodb_buffer_pool_size` includes the memory allocated for the block descriptors, the minimum is effectively `innodb_buffer_pool_size=6m`.

> **Tip:**
>
> When the buffer pool is shrunk, InnoDB tries to inform the operating system that the underlying memory for part of the virtual address range is no longer needed and may be zeroed out. On many POSIX-like systems this is done by `madvise(MADV_DONTNEED)` where available (Linux, FreeBSD, NetBSD, OpenBSD, Dragonfly BSD, IBM AIX, Apple macOS). On Microsoft Windows, `VirtualFree(MEM_DECOMMIT)` is invoked. On many systems, there is also `MADV_FREE`, which would be a deferred variant of `MADV_DONTNEED`, not freeing the virtual memory mapping immediately. We prefer immediate freeing so that the resident set size of the process reflects the current `innodb_buffer_pool_size` value. Shrinking the buffer pool is a rarely executed intensive operation, and the immediate configuration of the MMU mappings should not incur significant additional penalty.

The `Innodb_buffer_pool_resize_status` variable is removed. Issuing `SET GLOBAL innodb_buffer_pool_size` blocks until the buffer pool has been resized or the operation was aborted by a `KILL` or `SHUTDOWN` command, a client disconnect, or an interrupt.

innodb_old_blocks_pct and innodb_old_blocks_time

The default 37% reserved for the old list can be adjusted by changing the value of innodb_old_blocks_pct. It can accept anything between 5% and 95%.

The innodb_old_blocks_time variable specifies the delay before a block can be moved from the old to the new sublist. `0` means no delay, while the default has been set to `1000`.

Before changing either of these values from their defaults, make sure you understand the impact and how your system currently uses the buffer. Their main reason for existence is to reduce the impact of full table scans, which are usually infrequent, but large, and previously could clear everything from the buffer. Setting a non-zero delay could help in situations where full table scans are performed in quick succession.

Temporarily changing these values can also be useful to avoid the negative impact of a full table scan, as explained in InnoDB logical backups.

Dumping and Restoring the Buffer Pool

When the server starts, the buffer pool is empty. As it starts to access data, the buffer pool will slowly be populated. As more data are accessed, the most frequently accessed data are put into the buffer pool, and old data may be evicted. This means that a certain period of time is necessary before the buffer pool is really useful. This period of time is called the warmup.

InnoDB can dump the buffer pool before the server shuts down, and restore it when it starts again. If this feature is used, no warmup is necessary. Use the innodb_buffer_pool_dump_at_shutdown and innodb_buffer_pool_load_at_startup system variables to enable or disable the buffer pool dump at shutdown and the restore at startup respectively.

It is also possible to dump the InnoDB buffer pool at any moment while the server is running, and it is possible to restore the last buffer pool dump at any moment. To do this, the special innodb_buffer_pool_dump_now and innodb_buffer_pool_load_now system variables can be set to ON. When selected, their value is always OFF.

A buffer pool restore, both at startup or at any other moment, can be aborted by setting innodb_buffer_pool_load_abort to ON.

The file which contains the buffer pool dump is specified via the innodb_buffer_pool_filename system variable.

InnoDB Change Buffering

> **Warning:**
>
> The change buffer has been disabled by default from MariaDB 10.5.15, MariaDB 10.6.7, MariaDB 10.7.3 and MariaDB 10.8.2 (MDEV-27734), was deprecated and ignored from MariaDB 10.9.0 (MDEV-27735), and was removed in MariaDB 11.0.0 (MDEV-29694).

Benchmarks attached to MDEV-19514 show that the change buffer sometimes reduces performance, and in the best case seem to bring a few per cent improvement to throughput. However, such improvement could come with a price: If the buffered changes are never merged (MDEV-19514, motivated by the reduction of random crashes and the removal of an innodb_force_recovery option that can inflict further corruption), then the InnoDB system tablespace can grow out of control (MDEV-21952).

`INSERT`, `UPDATE`, and `DELETE` statements can be particularly heavy operations to perform, as all indexes need to be updated after each change. For this reason these changes are often buffered.

Pages are modified in the buffer pool, and not immediately on disk. After all the records that cover the changes to a data page have been written to the InnoDB redo log, the changed page may be written (''flushed'') to a data file. Pages that have been modified in memory and not yet flushed are called dirty pages.

The Change Buffer is an optimization that allows some data to be modified even though the data page does not exist in the buffer pool. Instead of modifying the data in its final destination, we would insert a record into a special Change Buffer that resides in the system tablespace. When the page is read into the buffer pool for any reason, the buffered changes are applied to it.

The Change Buffer only contains changes to secondary index leaf pages.

In the days of old, only inserted rows could be buffered, so this buffer was called *Insert Buffer*. The old name still appears in several places, for example in the output of SHOW ENGINE INNODB STATUS.

Inserts to `UNIQUE` secondary indexes cannot be buffered unless unique_checks=0 is used. This may sometimes allow duplicates to be inserted into the `UNIQUE` secondary index. Much of the time, the `UNIQUE` constraint would be checked because the change buffer could only be used if the index page is not located in the buffer pool.

When rows are deleted, a flag is set, thus rows are not immediately deleted. Delete-marked records may be purged after the transaction has been committed and any read views that were created before the commit have been closed. Delete-mark and purge buffering of any secondary indexes is allowed.

`ROLLBACK` never makes use of the change buffer; it would force a merge of any changes that were buffered during the execution of the transaction.

The Change Buffer is an optimization because:

- Some random-access page reads are transformed into modifications of change buffer pages.
- A change buffer page can be modified several times in memory and be flushed to disk only once.
- Dirty pages are flushed together, so the number of IO operations is lower.

If the server crashes or is shut down, the Change Buffer might not be empty. The Change Buffer resides in the InnoDB system tablespace, covered by the write-ahead log, so they can be applied at server restart. A shutdown with innodb_fast_shutdown=0 will merge all buffered changes.

There is no background task that merges the change buffer to the secondary index pages. Changes are only merged on demand.

> **Warning:**
>
> The Change Buffer was removed in MariaDB 11.0 because it has been a prominent source of corruption bugs that have been extremely hard to reproduce.

The main server system variable here is innodb_change_buffering, which determines which form of change buffering, if any, to use.

The following settings are available:

- inserts
  - Only buffer insert operations
- deletes
  - Only buffer delete operations
- changes
  - Buffer both insert and delete operations

- purges
  - Buffer the actual physical deletes that occur in the background
- all
  - Buffer inserts, deletes and purges. Default setting from MariaDB 5.5 until MariaDB 10.5.14, MariaDB 10.6.6, MariaDB 10.7.2 and MariaDB 10.8.1.
- none
  - Don't buffer any operations. Default from MariaDB 10.5.15, MariaDB 10.6.7, MariaDB 10.7.3 and MariaDB 10.8.2.

Modifying the value of this variable only affects the buffering of new operations. The merging of already buffered changes is not affected.

The innodb_change_buffer_max_size system variable determines the maximum size of the change buffer, expressed as a percentage of the buffer pool.

InnoDB Data Scrubbing

> **Warning:**
>
> Most of the background and redo log scrubbing code has been removed in MariaDB 10.5.2. See MDEV-15528 and MDEV-21870.

Sometimes there is a requirement that when some data is deleted, it is really gone. This might be the case when one stores user's personal information or some other sensitive data. Normally though, when a row is deleted, the space is only marked as free on the page. It may eventually be overwritten, but there is no guarantee when that will happen. A copy of the deleted rows may also be present in the log files.

Support for InnoDB data scrubbing: Background threads periodically scan tablespaces and logs and remove all data that should be deleted. The number of background threads for tablespace scans is set by innodb-encryption-threads. Log scrubbing happens in a separate thread.

To configure scrubbing one can use the following variables:

innodb-background-scrub-data-check-interval	Seconds	Check at this interval if tablespaces needs scrubbing. Deprecated and ignored.
innodb-background-scrub-data-compressed	Boolean	Enable scrubbing of compressed data by background threads. Deprecated and ignored.
innodb-background-scrub-data-interval	Seconds	Scrub spaces that were last scrubbed longer than this many seconds ago. Deprecated and ignored.
innodb-background-scrub-data-uncompressed	Boolean	Enable scrubbing of uncompressed data by background threads. Deprecated and ignored.
innodb-immediate-scrub-data-uncompressed	Boolean	Enable scrubbing of uncompressed data.
innodb-scrub-log	Boolean	Enable redo log scrubbing. Deprecated and ignored.
innodb-scrub-log-speed	Bytes/sec	Redo log scrubbing speed in bytes/sec. Deprecated and ignored.

Redo log scrubbing did not fully work as intended, and was deprecated and ignored in MariaDB 10.5.2 (MDEV-21870). If old log contents should be kept secret, enabling innodb_encrypt_log or setting a smaller innodb_log_file_size could help.

The Information Schema INNODB_TABLESPACES_SCRUBBING table contains scrubbing information.

Thanks

- Scrubbing was donated to the MariaDB project by Google.

InnoDB Doublewrite Buffer

The InnoDB doublewrite buffer was implemented to recover from half-written pages. This can happen when there's a power failure while InnoDB is writing a page to disk. On reading that page, InnoDB can discover the corruption from the mismatch of the page checksum. However, in order to recover, an intact copy of the page would be needed.

The double write buffer provides such a copy.

Whenever InnoDB flushes a page to disk, it is first written to the double write buffer. Only when the buffer is safely flushed to disk will InnoDB write the page to the final destination. When recovering, InnoDB scans the double write buffer and for each valid page in the buffer checks if the page in the data file is valid too.

Doublewrite Buffer Settings

To turn off the doublewrite buffer, set the innodb_doublewrite system variable to `0`. This is safe on filesystems that write pages atomically - that is, a page write fully succeeds or fails. But with other filesystems, it is not recommended for production systems. An alternative option is atomic writes. See atomic write support for more details.

InnoDB Flush Method

> **Note:**
>
> The `innodb_flush_method` variable has been deprecated from MariaDB 11.0.

> **Note:**
>
> For the OS-level mechanisms behind the values used on this page (`fdatasync()`, `fsync()`, `O_DIRECT`, `O_DSYNC`, and their Windows counterparts), see Storage I/O: Buffering and Persistence.

Overview

innodb_flush_method is a variable that has been available in MariaDB (and MySQL) for a long time. It defines the method used to flush data to InnoDB data files and log files, which can affect I/O throughput quite a bit.

The default setting for this variable initially was `fsync`, but was changed to `O_DIRECT` in MariaDB 10.6. The variable has been deprecated in MariaDB 11.0 and replaced by other settings.

This page describes the main settings and examines when it makes sense or not to change the default values.

Options and Startup Variables

First of all, let's look at what the different options for `innodb_flush_method` mean, and how they map to the new Boolean options that can be changed while the server is running. Those new options are available from MariaDB

11.0. There are 2 sets of Boolean options, controlling how the InnoDB write-ahead log `ib_logfile0` as well as the persistent data files are written:

1. `innodb_data_file_write_through`, `innodb_log_file_write_through`: Controls if each write is made durable without an additional system call, such as `fdatasync()` or `fsync()`. This can be useful if there is a battery-backed cache, or if the storage stack can make efficient use of FUA[7].
2. `innodb_data_file_buffering`, `innodb_log_file_buffering`: Controls if the operating system's file system cache is used. Those options are disabled by default, to allow efficient writes by DMA[8] from an aligned memory buffer. Starting with MariaDB Server 10.8, the log block size adapts to the underlying physical block size (typically 512 or 4096 bytes), to avoid an inefficient read-before-write anomaly. This is handled via the `innodb_log_write_ahead_size` variable (MDEV-33894).

The non-default setting `innodb_flush_method=O_DSYNC` disables buffering and enables write-through on all persistent InnoDB files. On suitable hardware, this can provide the best write performance.

The old default setting `innodb_flush_method=fsync` disables write-through and enables `innodb_data_file_buffering=ON`. The setting of `innodb_log_file_buffering` is not affected. The settings `littlesync` and `nosync`, as well as the Microsoft Windows setting `normal` are treated in the same way.

The MariaDB Server 10.6 default setting `innodb_flush_method=O_DIRECT` leaves the new Boolean options at their default values. On Microsoft Windows, this option is also known as `unbuffered` and `async_unbuffered`.

The unsafe setting `innodb_flush_method =O_DIRECT_NO_FSYNC` is treated like `O_DIRECT`. You can disable any use of `fdatasync()` or `fsync()` system calls, but that means you lose all crash-safety guarantees. To do that, set `debug-no-sync =ON`. Starting with MariaDB Server 11.0, this unsafe variable affects InnoDB as well.

> **Note:**
>
> **Effects of bypassing the file system buffering:**
>
> When file system buffering is bypassed, InnoDB attempts to open the file in `O_DIRECT` mode (on Windows, with `FILE_FLAG_NO_BUFFERING`) if the file system supports that. When buffering is enabled or direct I/O is not supported, a file system cache can be maintained by the operating system kernel. This cache can make some read workloads much faster — some read workloads significantly benefit from setting `innodb_data_file_buffering=ON` (effectively disabling `O_DIRECT`).

Behavior Change in MariaDB 10.6

Let's now look at why the default behavior was changed in 10.6. Looking at how most modern file systems handle writes, it seems clear that the penalty of writing twice (to the file system cache and then to the disk) is not needed, and typically slows down the system. With `O_DIRECT`, there is no such double writing, as everything goes straight to disk.

However, there are still cases where reads are affected negatively by using `O_DIRECT`. Note that this only affects I/O-bound workloads. Ideally, a requested data page is cached in an internal MariaDB buffer (in this case the, InnoDB buffer pool), and the data can be accessed without involving the operating system, no matter how the data is written to disk.

There is a possibility that a data page is written from the buffer pool to the file system, evicted from the buffer pool, and again read from the file system. In this kind of scenario, the operating system could provide an additional layer of cache between the buffer pool and the storage, allowing the "read" to be a simple matter of copying the data from the kernel buffer to the buffer pool. The worst-case scenario is that the page needs to be read from actual storage, which can be orders of magnitude slower than copying from the file system cache.

If `innodb_buffer_pool_size` is very small compared to the available memory, the file system cache may effectively become the main cache. This can be useful when a MariaDB Server instance is small, or used sporadically on a

system that runs many other services. In such an environment, it can make sense to use `innodb_flush_method=fsync`, and to let the operating system tune the use of buffers according to the variable workload. From its early days decades ago, the Linux kernel tries to use all “free” memory for the file system cache.

Another thing to consider is read-ahead, or loading data into a cache in the anticipation of it being needed soon. While read-ahead mechanisms into the InnoDB buffer pool exist, the read-ahead into the Linux file system cache may perform much better. Part of the problem can be that MariaDB always reads InnoDB pages one at a time, giving an advantage to the operating system’s file system cache.

To summarize: Changing the default of `innodb_flush_method` to `O_DIRECT` in MariaDB 10.6 was the right choice — however, there are cases illustrated above where you might want to change this behavior back to the original one.

Behavior Change in MariaDB 11.0

> **Note:**
>
> The `innodb_flush_method` variable has been deprecated, but can still be used. The preferred way to use it is by setting one of the Boolean variables via the `SET GLOBAL` statement. The usage of those variables is explained in the Options and Startup Variables section.

From MariaDB 11.0, the flushing behavior of InnoDB should no longer be controlled by `innodb_flush_method`, but rather by the following variables, which can be modified with a `SET GLOBAL` statement while the server is running:

1. `innodb_log_file_buffering`: This is best left to its default value (`OFF`), except when backing up a write-heavy server.
2. `innodb_data_file_buffering`: The default is `OFF`; set it to `ON` if you encounter read performance problems.
3. `innodb_log_file_write_through`, `innodb_data_file_write_through`: The default is `OFF` for both variables; setting them to `ON` can improve or degrade write performance, depending on whether or not the hardware supports FUA (Forced Unit Access).

> **Note:**
>
> A `SET GLOBAL` change to `innodb_log_file_buffering` or `innodb_log_file_write_through` can be silently ignored — for example, while an `innodb_log_file_size` resize is in progress, or when the log is mapped to persistent memory (PMEM). Confirm the change took effect by reading the value back, as described for `innodb_log_file_buffering` and `innodb_log_file_write_through`.

FUA (Forced Unit Access)

FUA is a hardware-level flag used during write operations to ensure data integrity. When InnoDB sends a write command with the FUA flag, it tells the storage device (SSD or HDD) that the write must be written directly to the non-volatile, stable media before the device can report that the task is finished.

> **Warning:**
>
> FUA only works if your hardware (and its drivers) actually supports it. Some cheaper consumer SSDs claim to support FUA but secretly ignore it to make their benchmark speeds look faster — this can lead to data corruption during a power failure!

InnoDB is a transactional storage engine, meaning it promises that once a transaction is committed, it won’t be lost even if the power goes out. To keep this promise, InnoDB has to flush data from the computer’s RAM to the physical disk. Traditionally, this involved two steps:

1. Write: Send data to the disk (where it might sit in the disk’s own temporary cache).
2. `fsync`: Send a separate command telling the disk to push everything in the cache to the physical disk.

FUA combines these into one step. By using FUA, InnoDB instructs the operation system to write out data and demands that success is only reported when that data is safe on the physical media.

This has these benefits:

- Performance: It eliminates the need for a second `fsync` system call, which can reduce latency and CPU overhead.
- Efficiency: FUA is fine-grained. Instead of forcing the disk to flush its *entire* cache (which `fsync` does), FUA only forces the specific block of data you are currently writing.

Starting with MariaDB 10.6, the way InnoDB handles flushing changed significantly. See this section for details.

FUA can be detrimental for data file write performance, but beneficial for log writes. For the latter, set `innodb_data_file_write_through` to `OFF` to improve write performance.

InnoDB Lock Modes

Locks are acquired by a transaction to prevent concurrent transactions from modifying, or even reading, some rows or ranges of rows. This is done to make sure that concurrent write operations never collide.

InnoDB supports a number of lock modes.

Shared and Exclusive Locks

The two standard row-level locks are *share locks*(S) and *exclusive locks*(X).

A shared lock is obtained to read a row, and allows other transactions to read the locked row, but not to write to the locked row. Other transactions may also acquire their own shared locks.

An exclusive lock is obtained to write to a row, and stops other transactions from locking the same row. It's specific behavior depends on the isolation level; the default (REPEATABLE READ), allows other transactions to read from the exclusively locked row.

Locks Apply to Index Records, Not Logical Table Rows

In InnoDB, when using `LOCK IN SHARE MODE` under the `READ COMMITTED` isolation level, it is critical to understand that locking reads are based on index records and not on abstract table rows. This difference is important, when using locking reads like these:

```
SELECT ... LOCK IN SHARE MODE;
SELECT ... FOR UPDATE;
```

InnoDB's locking engine works at the index record level, but a query logically focuses on a row. Therefore, based on the isolation level and data creation order, lock conflicts can be avoided if two simultaneous transactions access the same row through different indexes.

Index Reads and Lock Behavior

When a secondary index matches a transaction, InnoDB:

- Reads only the secondary index
- locks the secondary index records
- Avoids accessing the primary index record

If another transaction alters a column that is not included in the secondary index, only the primary index record can be locked. In that case, the two transactions lock different index records without blocking each other.

Example

The following scenario illustrates a case where `SELECT ... LOCK IN SHARE MODE` does not prevent a concurrent update, even though both statements refer to the same logical rows:

```
CREATE TABLE tbl_1 (
  col_1_1 TIMESTAMP,
  col_1_2 VARCHAR(100),
  col_1_3 MEDIUMINT,
  col_1_4 INT,
  col_1_5 DOUBLE,
  col_1_6 NUMERIC,
  pkid_1 INT,
  INDEX idx_1_1 (col_1_4, col_1_2, col_1_3, col_1_5),
  PRIMARY KEY (col_1_4, pkid_1)
) ENGINE=InnoDB;
```

Here:

- `PRIMARY KEY (col_1_4, pkid_1)` -> Clustered Index (Primary Index Record)
- `INDEX idx_1_1 (col_1_4, col_1_2, col_1_3, col_1_5)` -> Secondary Index (Secondary Index Record)

Sample Data

```
INSERT INTO tbl_1 VALUES
('2025-12-19 16:46:56','str_002',2,3,1,1,0),
('2025-12-19 16:46:56','str_002',2,3,2,1,1),
('2025-12-19 16:46:57','str_002',1,3,2,1,2),
('2025-12-19 16:46:56','str_002',1,3,2,1,3),
('2025-12-19 16:46:57','str_002',1,3,2,1,4),
('2025-12-19 16:46:56','str_002',1,1,2,1,5),
('2025-12-19 16:46:56','str_002',1,2,2,1,6);
```

Connection 1

```
SET SESSION TRANSACTION ISOLATION LEVEL READ COMMITTED;
BEGIN;

SELECT col_1_4, col_1_2, pkid_1 FROM tbl_1 WHERE col_1_3 > 1 LOCK IN SHARE MODE;
```

What happens

- The query makes use of the secondary index `idx_1_1`.
- The query reads `col_1_4`, `col_1_2`, and `pkid_1`, which are part of `idx_1_1`.
- This is a covering or secondary index read.
- InnoDB skips the primary index and only applies shared locks to records in `idx_1_1`.

Default Connection (Concurrent)

```
SET SESSION TRANSACTION ISOLATION LEVEL READ COMMITTED;
BEGIN;

UPDATE tbl_1
SET col_1_1 = '2025-12-19 16:46:56'
WHERE col_1_4 = 3;
```

What happens

- The `UPDATE` changes `col_1_1`, which is not present in `idx_1_1`.
- The PRIMARY KEY record must be locked in InnoDB.
- No changes to `idx_1_1` are required.

Why No Blocking Occurs

1. Connection 1's `SELECT` performs a "covering read" on the secondary index `idx_1_1`. Since the index contains all required data, InnoDB only uses shared locks on secondary index records.
2. Default Connection's `UPDATE` modifies column `col_1_1`, which is not part of that secondary index. Therefore, an exclusive lock is acquired on the Primary Index record (Clustered Index).
3. The Result: Since these are two different index records, there is no conflict between the shared and exclusive locks.

How to Ensure Blocking

To cause a lock conflict, the locking read must access the primary key record (Clustered Index). This ensures that the *shared lock* (S) is applied to the location where the update operation (exclusive lock, X) will later be required. This happens when:

- The SELECT contains a column that the secondary index does not cover (e.g., using `SELECT *` or selecting a non-indexed column), or
- If the secondary index itself is insufficient to satisfy the query, InnoDB must access the full row in the primary index, thereby placing the necessary locks to ensure blocking.

Example:

```
-- The UPDATE is blocked since col_1_1 is not included in the secondary index idx_1_1.
SELECT col_1_1, col_1_4, pkid_1
FROM tbl_1
WHERE col_1_3 > 1
LOCK IN SHARE MODE;
```

The UPDATE will now wait while the clustered index is accessed.

Intention Locks

InnoDB also permits table locking, and to allow locking at both table and row level to co-exist gracefully, a series of locks called *intention locks* exist.

An *intention shared lock*(IS) indicates that a transaction intends to set a shared lock.

An *intention exclusive lock*(IX) indicates that a transaction intends to set an exclusive lock.

Whether a lock is granted or not can be summarised as follows:

- An X lock is not granted if any other lock (X, S, IX, IS) is held.
- An S lock is not granted if an X or IX lock is held. It is granted if an S or IS lock is held.
- An IX lock is not granted if in X or S lock is held. It is granted if an IX or IS lock is held.
- An IS lock is not granted if an X lock is held. It is granted if an S, IX or IS lock is held.

AUTO_INCREMENT Locks

Locks are also required for auto-increments - see AUTO_INCREMENT handling in InnoDB.

Gap Locks

With the default isolation level, `REPEATABLE READ`, and, until MariaDB 10.4, the default setting of the innodb_locks_unsafe_for_binlog variable, a method called gap locking is used. When InnoDB sets a shared or exclusive lock on a record, it's actually on the index record. Records will have an internal InnoDB index even if they don't have a unique index defined. At the same time, a lock is held on the gap before the index record, so that another transaction cannot insert a new index record in the gap between the record and the preceding record.

The gap can be a single index value, multiple index values, or not exist at all depending on the contents of the index.

If a statement uses all the columns of a unique index to search for unique row, gap locking is not used.

Similar to the shared and exclusive intention locks described above, there can be a number of types of gap locks. These include the shared gap lock, exclusive gap lock, intention shared gap lock and intention exclusive gap lock.

Gap locks are disabled if the innodb_locks_unsafe_for_binlog system variable is set (until MariaDB 10.4), or the isolation level is set to `READ COMMITTED`.

InnoDB Log Archiving

> **Note:**
>
> This functionality is available from MariaDB 13.0.

Overview

By default, the InnoDB write-ahead log is managed as a ring buffer in a single file (`ib_logfile0`). This is efficient for write performance, but log records are eventually overwritten as the ring wraps, which limits the options for point-in-time recovery (PITR) and incremental backups.

InnoDB log archiving replaces the ring buffer with a sequence of pre-allocated, sequentially-named log files. When one file fills up, the server creates the next. Once a checkpoint completes in a new file, the previous file is marked read-only — at which point you can safely move it to long-term storage. The result is a continuous log history for the period archiving was active.

> **Warning:**
>
> No shipped backup tool yet generates or restores backups in the `innodb_log_archive=ON` format. `mariadb-backup` only supports the legacy `ib_logfile0` format and fails when the server is running with `innodb_log_archive=ON`. A backup tool that uses this format is being worked on.

Enabling Log Archiving

To enable log archiving, set the `innodb_log_archive` system variable to `ON`. This variable is dynamic and can be changed while the server is running:

```
SET GLOBAL innodb_log_archive=ON;
```

When archiving is active, the server creates files in the data directory using the naming convention `ib_`*`lsn`*`.log`, where *lsn* is a 16-character hexadecimal value identifying the log sequence number that maps to file offset `0x3000` (12288) — the start of record payload within each file.

File Format

Each archive log file has a 12 KiB header. Completed checkpoints in the file are recorded in this header as 64-bit big-endian offsets to a `FILE_MODIFY` / `FILE_CHECKPOINT` mini-transaction within the file. With `innodb_encrypt_log=OFF`, the header can hold up to 1536 checkpoint slots; if a file produces more checkpoints than that, further checkpoints overwrite the last slot until the next log file is started.

Technical Constraints

- **Log file size:** When `innodb_log_archive` is `ON`, changes to `innodb_log_file_size` take effect when the current log file fills up and a new file is created. There is no special upper bound on `innodb_log_file_size` in

this mode.

- **Encryption:** While `innodb_log_archive` is `ON`, `innodb_encrypt_log` and related encryption parameters cannot be changed. Each `ib_lsn.log` file must use the same encryption parameters. To change encryption, set `innodb_log_archive=OFF` and restart the server — this permanently discards the archived log history.
- **Startup:** With `innodb_log_archive=ON`, the server refuses to start if `ib_logfile0` exists in the data directory.
- **Data Dictionary:** Log archiving tracks changes to InnoDB tables. It does not cover `.frm` files or other non-InnoDB metadata, which means point-in-time recovery of DDL operations is limited.

Inspecting the Archive State

When `innodb_log_archive=ON`, both the `innodb_log_archive` system variable and the `Innodb_lsn_archived` status variable remain constant by design. `Innodb_lsn_archived` reports the LSN since which a complete InnoDB log archive is available — that is, the first checkpoint in the first archived log file — and does not advance as new log records are written. It is the static lower bound of the archive.

What does advance during normal operation are the `Innodb_lsn_current` status variable (the LSN of the most recent log write) and the `Innodb_lsn_last_checkpoint` status variable (the LSN of the most recent completed checkpoint). Query these to observe ongoing log activity:

```
SELECT @@GLOBAL.innodb_log_archive AS archiving;

SELECT VARIABLE_NAME, VARIABLE_VALUE
FROM   INFORMATION_SCHEMA.GLOBAL_STATUS
WHERE  VARIABLE_NAME IN ('INNODB_LSN_ARCHIVED',
                         'INNODB_LSN_CURRENT',
                         'INNODB_LSN_LAST_CHECKPOINT');
```

Managing Archived Log Files

Once a checkpoint completes in a new log file, the previous file is marked read-only. You can safely move read-only `ib_lsn.log` files to offline storage.

> **Warning:**
>
> Before *deleting* an archived log file, check that `Innodb_lsn_last_checkpoint` is not older than the start LSN embedded in the first writable `ib_lsn.log` file. If it is, crash recovery still requires the previous log file — deleting it leaves the server unable to recover.

Performing Recovery from Archived Logs

The startup parameters `innodb_log_recovery_start` and `innodb_log_recovery_target` define the range of the log replay. Both default to `0`:

- `innodb_log_recovery_start=0` means start from the latest completed checkpoint (always present in one of the last two `ib_lsn.log` files).
- `innodb_log_recovery_target=0` means replay to the end of the available log.

See Point-In-Time Recovery (InnoDB log archiving) for the full procedure.

InnoDB Monitors

The InnoDB Monitor refers to particular kinds of monitors included in MariaDB and since the early versions of MySQL.

There are four types: the standard InnoDB monitor, the InnoDB Lock Monitor, InnoDB Tablespace Monitor and the InnoDB Table Monitor.

Standard InnoDB Monitor

The standard InnoDB Monitor returns extensive InnoDB information, particularly lock, semaphore, I/O and buffer activity:

To enable the standard InnoDB Monitor, from MariaDB 10.0.14, set the innodb_status_output system variable to 1. Before MariaDB 10.0.14, running the following statement was the method used:

```
CREATE TABLE innodb_monitor (a INT) ENGINE=INNODB;
```

To disable the standard InnoDB monitor, either set the system variable to zero, or, before MariaDB 10.0.14, drop the table

```
DROP TABLE innodb_monitor;
```

The CREATE TABLE and DROP TABLE method of enabling and disabling the InnoDB Monitor has been deprecated, and may be removed in a future version of MariaDB.

For a description of the output, see SHOW ENGINE INNODB STATUS.

InnoDB Lock Monitor

The InnoDB Lock Monitor displays additional lock information.

To enable the InnoDB Lock Monitor, the standard InnoDB monitor must be enabled. Then, from MariaDB 10.0.14, set the innodb_status_output_locks system variable to 1.
Before MariaDB 10.0.14, running the following statement was the method used:

```
CREATE TABLE innodb_lock_monitor (a INT) ENGINE=INNODB;
```

To disable the standard InnoDB monitor, either set the system variable to zero, or, before MariaDB 10.0.14, drop the table

```
DROP TABLE innodb_lock_monitor;
```

The CREATE TABLE and DROP TABLE method of enabling and disabling the InnoDB Lock Monitor has been deprecated, and may be removed in a future version of MariaDB.

InnoDB Tablespace Monitor

The InnoDB Tablespace Monitor is deprecated, and may be removed in a future version of MariaDB.

Enabling the Tablespace Monitor outputs a list of file segments in the shared tablespace to the error log, and validates the tablespace allocation data structures.

To enable the Tablespace Monitor, run the following statement:

```
CREATE TABLE innodb_tablespace_monitor (a INT) ENGINE=INNODB;
```

To disable it, drop the table:

```
DROP TABLE innodb_tablespace_monitor;
```

InnoDB Table Monitor

The InnoDB Table Monitor is deprecated, and may be removed in a future version of MariaDB.

Enabling the Table Monitor outputs the contents of the InnoDB internal data dictionary to the error log every fifteen seconds.

To enable the Table Monitor, run the following statement:

```
CREATE TABLE innodb_table_monitor (a INT) ENGINE=INNODB;
```

To disable it, drop the table:

```
DROP TABLE innodb_table_monitor;
```

SHOW ENGINE INNODB STATUS

The SHOW ENGINE INNODB STATUS statement can be used to obtain the standard InnoDB Monitor output when required, rather than sending it to the error log. It will also display the InnoDB Lock Monitor information if the innodb_status_output_locks system variable is set to `1`.

InnoDB Page Compression

Overview

InnoDB page compression provides a way to compress InnoDB tables.

Use Cases

- InnoDB page compression can be used on any storage device and any file system.
- InnoDB page compression is most efficient on file systems that support sparse files. See Saving Storage Space with Sparse Files for more information.
- InnoDB page compression is most beneficial on solid state drives (SSDs) and other flash storage. See Optimized for Flash Storage for more information.
- InnoDB page compression performs best when your storage device and file system support atomic writes, since that allows the InnoDB doublewrite buffer to be disabled. See Atomic Write Support for more information.

Comparison with the `COMPRESSED` Row Format

InnoDB page compression is a modern way to compress your InnoDB tables. It is similar to InnoDB's COMPRESSED row format, but it has many advantages. Some of the differences are:

- With InnoDB page compression, compressed pages are immediately decompressed after being read from the tablespace file, and only uncompressed pages are stored in the buffer pool. In contrast, with InnoDB's COMPRESSED row format, compressed pages are decompressed immediately after they are read from the tablespace file, and both the uncompressed and compressed pages are stored in the buffer pool. This means that the COMPRESSED row format uses more space in the buffer pool than InnoDB page compression does.
- With InnoDB page compression, pages are compressed just before being written to the tablespace file. In contrast, with InnoDB's COMPRESSED row format, pages are re-compressed immediately after any changes, and the compressed pages are stored in the buffer pool alongside the uncompressed pages. These changes are then occasionally flushed to disk. This means that the COMPRESSED row format re-compresses data more frequently than InnoDB page compression does.
- With InnoDB page compression, multiple compression algorithms are supported. In contrast, with InnoDB's COMPRESSED row format, zlib is the only supported compression algorithm. This means that the

COMPRESSED row format has less compression options than InnoDB page compression does.

In general, InnoDB page compression is superior to the COMPRESSED row format.

Comparison with Storage Engine-Independent Column Compression

- See Storage Engine-Independent Column Compression - Comparison with InnoDB Page Compression.

Configuring the InnoDB Page Compression Algorithm

There is not currently a table option to set different InnoDB page compression algorithms for individual tables.

However, the server-wide InnoDB page compression algorithm can be configured by setting the innodb_compression_algorithm system variable.

When this system variable is changed, the InnoDB page compression algorithm does not change for existing pages that were already compressed with a different InnoDB page compression algorithm. InnoDB is able to handle this situation without issues, because every page in an InnoDB tablespace contains metadata about the InnoDB page compression algorithm in the page header. This means that InnoDB supports having uncompressed pages and pages compressed with different InnoDB page compression algorithms in the same InnoDB tablespace at the same time.

This system variable can be set to one of the following values:

System Variable Value	Description
none	Pages are not compressed. This is the default value in MariaDB 10.2.3 and before, and MariaDB 10.1.21 and before.
zlib	Pages are compressed using the bundled zlib compression algorithm. This is the default value in MariaDB 10.2.4 and later, and MariaDB 10.1.22 and later.
lz4	Pages are compressed using the lz4 compression algorithm.
lzo	Pages are compressed using the lzo compression algorithm.
lzma	Pages are compressed using the lzma compression algorithm.
bzip2	Pages are compressed using the bzip2 compression algorithm.
snappy	Pages are compressed using the snappy algorithm.

However, on many distributions, the standard MariaDB builds do not support all InnoDB page compression algorithms by default. From MariaDB 10.7, algorithms can be installed as a plugin.

This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_compression_algorithm='lzma';
```

This system variable can also be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_compression_algorithm=lzma
```

Checking Supported InnoDB Page Compression Algorithms

On many distributions, the standard MariaDB builds do not support all InnoDB page compression algorithms by default. Therefore, if you want to use a specific InnoDB page compression algorithm, then you should check whether your MariaDB build supports it.

The zlib compression algorithm is always supported. From MariaDB 10.7, algorithms can be installed as a plugin.

A MariaDB build's support for other InnoDB page compression algorithms can be checked by querying the following status variables with SHOW GLOBAL STATUS:

Status Variable	Description
Innodb_have_lz4	Whether InnoDB supports the lz4 compression algorithm.
Innodb_have_lzo	Whether InnoDB supports the lzo compression algorithm.
Innodb_have_lzma	Whether InnoDB supports the lzma compression algorithm.
Innodb_have_bzip2	Whether InnoDB supports the bzip2 compression algorithm.
Innodb_have_snappy	Whether InnoDB supports the snappy compression algorithm.

For example:

```
SHOW GLOBAL STATUS WHERE Variable_name IN (
   'Innodb_have_lz4',
   'Innodb_have_lzo',
   'Innodb_have_lzma',
   'Innodb_have_bzip2',
   'Innodb_have_snappy'
);
+--------------------+-------+
| Variable_name      | Value |
+--------------------+-------+
| Innodb_have_lz4    | OFF   |
| Innodb_have_lzo    | OFF   |
| Innodb_have_lzma   | ON    |
| Innodb_have_bzip2  | OFF   |
| Innodb_have_snappy | OFF   |
+--------------------+-------+
```

Adding Support for an InnoDB Page Compression Algorithm

On many distributions, the standard MariaDB builds do not support all InnoDB page compression algorithms by default. From MariaDB 10.7, algorithms can be installed as a plugin, but in earlier versions, if you want to use certain InnoDB page compression algorithms, then you may need to do the following:

- Download the package for the desired compression library from the above links.
- Install the package for the desired compression library.
- Compile MariaDB from the source distribution.

The general steps for compiling MariaDB are:

- Download and unpack the source code distribution:

```
wget https://downloads.mariadb.com/MariaDB/mariadb-10.4.8/source/mariadb-10.4.8.tar.gz
tar -xvzf mariadb-10.4.8.tar.gz
cd mariadb-10.4.8/
```

- Configure the build using cmake:

```
cmake .
```

- Check CMakeCache.txt to confirm that it has found the desired compression library on your system.
- Compile the build:

```
make
```

- Either install the build:

```
make install
```

Or make a package to install:

```
make package
```

See Compiling MariaDB From Source for more information.

Enabling InnoDB Page Compression

InnoDB page compression is not enabled by default. However, InnoDB page compression can be enabled for just individual InnoDB tables or it can be enabled for all new InnoDB tables by default.

InnoDB page compression is also only supported if the InnoDB table is in a file per-table tablespace. Therefore, the innodb_file_per_table system variable must be set to `ON` to use InnoDB page compression.

InnoDB page compression is only supported if the InnoDB table uses the `Barracuda` file format.Therefore, in MariaDB 10.1 and before, the innodb_file_format system variable must be set to `Barracuda` to use InnoDB page compression.

InnoDB page compression is also only supported if the InnoDB table's row format is COMPACT or DYNAMIC.

Enabling InnoDB Page Compression by Default

In MariaDB 10.2.3 and later, InnoDB page compression can be enabled for all new InnoDB tables by default by setting the innodb_compression_default system variable to `ON`.

This system variable can be set to one of the following values:

System Variable Value	Description
OFF	New InnoDB tables do not use InnoDB page compression. This is the default value.
ON	New InnoDB tables use InnoDB page compression.

This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_compression_default=ON;
```

This system variable's session value can be changed dynamically with SET SESSION:

```
SET GLOBAL innodb_file_per_table=ON;

SET GLOBAL innodb_file_format='Barracuda';

SET GLOBAL innodb_default_row_format='dynamic';

SET GLOBAL innodb_compression_algorithm='lzma';

SET SESSION  innodb_compression_default=ON;

CREATE TABLE users (
   user_id INT NOT NULL,
   b VARCHAR(200),
   PRIMARY KEY(user_id)
)
   ENGINE=InnoDB;
```

This system variable can also be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_compression_default=ON
```

Enabling InnoDB Page Compression for Individual Tables

InnoDB page compression can be enabled for individual tables by setting the PAGE_COMPRESSED table option to `1`:

```
SET GLOBAL innodb_file_per_table=ON;

SET GLOBAL innodb_file_format='Barracuda';

SET GLOBAL innodb_default_row_format='dynamic';

SET GLOBAL innodb_compression_algorithm='lzma';

CREATE TABLE users (
   user_id INT NOT NULL,
   b VARCHAR(200),
   PRIMARY KEY(user_id)
)
   ENGINE=InnoDB
   PAGE_COMPRESSED=1;
```

Configuring the Compression Level

Some InnoDB page compression algorithms support a compression level option, which configures how the InnoDB page compression algorithm will balance speed and compression.

The compression level's supported values range from `1` to `9`. The range goes from the fastest to the most compact, which means that `1` is the fastest and `9` is the most compact.

Only the following InnoDB page compression algorithms currently support compression levels:

- zlib
- lzma

If an InnoDB page compression algorithm does not support compression levels, then it ignores any provided compression level value.

Configuring the Default Compression Level

The default compression level can be configured by setting the innodb_compression_level system variable.

This system variable's default value is `6`.

This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_compression_level=9;
```

This system variable can also be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_compression_level=9
```

Configuring the Compression Level for Individual Tables

The compression level for individual tables can also be configured by setting the PAGE_COMPRESSION_LEVEL table option for the table:

```
SET GLOBAL innodb_file_per_table=ON;

SET GLOBAL innodb_file_format='Barracuda';

SET GLOBAL innodb_default_row_format='dynamic';

SET GLOBAL innodb_compression_algorithm='lzma';

CREATE TABLE users (
   user_id INT NOT NULL,
   b VARCHAR(200),
   PRIMARY KEY(user_id)
)
   ENGINE=InnoDB
   PAGE_COMPRESSED=1
   PAGE_COMPRESSION_LEVEL=9;
```

Configuring the Failure Threshold and Maximum Padding

InnoDB page compression can encounter compression failures.

InnoDB page compression's failure threshold can be configured. If InnoDB encounters more compression failures than the failure threshold, then it pads pages with zeroed out bytes before attempting to compress them as a way to reduce failures. If the failure rate stays above the failure threshold, then InnoDB pads pages with more zeroed out bytes in 128 byte increments.

InnoDB page compression's maximum padding can also be configured.

Configuring the Failure Threshold

The failure threshold can be configured by setting the innodb_compression_failure_threshold_pct system variable.

This system variable's supported values range from `0` to `100`.

This system variable's default value is `5`.

This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_compression_failure_threshold_pct=10;
```

This system variable can also be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_compression_failure_threshold_pct=10
```

Configuring the Maximum Padding

The maximum padding can be configured by setting the innodb_compression_pad_pct_max system variable.

This system variable's supported values range from `0` to `75`.

This system variable's default value is `50`.

This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_compression_pad_pct_max=75;
```

This system variable can also be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_compression_pad_pct_max=75
```

Saving Storage Space with Sparse Files

When InnoDB page compression is used, InnoDB may still write the compressed page to the tablespace file with the original size of the uncompressed page, which would be equivalent to the value of the innodb_page_size system variable. This is done by design, because when InnoDB's I/O code needs to read the page from disk, it can only read the full page size. However, this is obviously not optimal.

On file systems that support sparse files, this problem is solved by writing the tablespace file as a sparse file using the *punch hole* technique. With the *punch hole* technique, InnoDB will only write the actual compressed page size to the tablespace file, aligned to sector size. The rest of the page is trimmed.

This *punch hole* technique allows InnoDB to read the compressed page from disk as the full page size, even though the compressed page really takes up less space on the file system.

There are some potential disadvantages to using sparse files:

- Some utilities may require special options in order to handle sparse files in an efficient manner.
- Most existing file systems are slow to unlink() sparse files. As a consequence, if a tablespace file is a sparse file, then dropping the table can be very slow.

Sparse File Support on Linux

On Linux, the following file systems support sparse files:

- `ext3`
- `ext4`
- `xfs`
- `btrfs`
- `nvmfs`

On Linux, file systems need to support the fallocate() system call with the `FALLOC_FL_PUNCH_HOLE` and `FALLOC_FL_KEEP_SIZE` flags:

```
fallocate(file_handle, FALLOC_FL_PUNCH_HOLE | FALLOC_FL_KEEP_SIZE, file_offset, remainder_len);
```

Some Linux utilities may require special options in order to work with sparse files efficiently:

- The ls utility will report the non-sparse size of the tablespace file when executed with default behavior, but ls -s will report the actual amount of storage allocated for the tablespace file.
- The cp utility is pretty good at auto-detecting sparse files, but it also provides the cp –sparse=always and cp –sparse=never options, if the auto-detection is not desired.
- The tar utility will archive sparse files with their non-sparse size when executed with default behavior, but tar –sparse will auto-detect sparse files, and archive them with their sparse size.

Sparse File Support on Windows

On Windows, the following file systems support sparse files:

- `NTFS`

On Windows, file systems need to support the DeviceIoControl() function with the FSCTL_SET_SPARSE and FSCTL_SET_ZERO_DATA control codes:

```
DeviceIoControl(file_handle, FSCTL_SET_SPARSE, inbuf, inbuf_size,
   outbuf, outbuf_size,  NULL, &overlapped)
...
DeviceIoControl(file_handle, FSCTL_SET_ZERO_DATA, inbuf, inbuf_size,
   outbuf, outbuf_size,  NULL, &overlapped)
```

Configuring InnoDB to use Sparse Files

In MariaDB 10.3 and later, InnoDB uses the *punch hole* technique to create sparse files used automatically when the underlying file system supports sparse files.

In MariaDB 10.2 and before, InnoDB can be configured to use the *punch hole* technique to create sparse files by configuring the innodb_use_trim and innodb_use_fallocate system variables. These system variables can be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_use_trim=ON
innodb_use_fallocate=ON
```

Optimized for Flash Storage

InnoDB page compression was designed to be optimized on solid state drives (SSDs) and other flash storage.

InnoDB page compression was originally developed by collaborating with Fusion-io. As a consequence, it was originally designed to work best on FusionIO devices using NVMFS. Fusion-io has since been acquired by Western Digital, and they have decided not to continue supporting NVMFS.

However, InnoDB page compression is still likely to be most optimized on solid state drives (SSDs) and other flash storage.

InnoDB page compression works without any issues on hard disk drives (HDDs). However, since its compression relies on the use of sparse files, the data may be somewhat fragmented on disk. This fragmentation may hurt performance on HDDs, since they handle random reads and writes much more slowly than flash storage.

Configuring InnoDB Page Flushing

With InnoDB page compression, pages are compressed when they are flushed to disk. Therefore, it can be helpful to optimize the configuration of InnoDB's page flushing. See InnoDB Page Flushing for more information.

Monitoring InnoDB Page Compression

InnoDB page compression can be monitored by querying the following status variables with SHOW GLOBAL STATUS:

Status Variable	Description
Innodb_page_compression_saved	Bytes saved by compression
Innodb_page_compression_trim_sect512	Number of 512 sectors trimmed
Innodb_page_compression_trim_sect1024	Number of 1024 sectors trimmed
Innodb_page_compression_trim_sect2048	Number of 2048 sectors trimmed
Innodb_page_compression_trim_sect4096	Number of 4096 sectors trimmed
Innodb_page_compression_trim_sect8192	Number of 8192 sectors trimmed
Innodb_page_compression_trim_sect16384	Number of 16384 sectors trimmed
Innodb_page_compression_trim_sect32768	Number of 32768 sectors trimmed
Innodb_num_pages_page_compressed	Number of pages compressed

Status Variable	Description
Innodb_num_page_compressed_trim_op	Number of trim operations
Innodb_num_page_compressed_trim_op_saved	Number of trim operations saved
Innodb_num_pages_page_decompressed	Number of pages decompressed
Innodb_num_pages_page_compression_error	Number of compression errors

With InnoDB page compression, a page is only compressed when it is flushed to disk. This means that if you are monitoring InnoDB page compression via these status variables, then the status variables values will only get incremented when the dirty pages are flushed to disk, which does not necessarily happen immediately:

```
CREATE TABLE `tab` (
     `id` INT(11) NOT NULL,
     `str` VARCHAR(50) DEFAULT NULL,
     PRIMARY KEY (`id`)
   ) ENGINE=InnoDB;

INSERT INTO tab VALUES (1, 'str1');

SHOW GLOBAL STATUS LIKE 'Innodb_num_pages_page_compressed';
+----------------------------------+-------+

Compatibility with Backup Tools

mariadb-backup supports InnoDB page compression.

Percona XtraBackup does not support InnoDB page compression.

Acknowledgements

- InnoDB page compression was developed by collaborating with Fusion-io. Special thanks especially to Dhananjoy Das and Torben Mathiasen.

InnoDB Page Flushing

InnoDB uses a single `buf_flush_page_cleaner` thread to flush dirty pages—modified pages that have not yet been written to data files—from the InnoDB buffer pool to disk. This thread handles page flushing regardless of the number of buffer pool instances. These dirty pages are flushed using a least-recently used (LRU) algorithm, which manages memory efficiently by prioritizing the eviction of older, less frequently accessed pages.

innodb_max_dirty_pages_pct

The innodb_max_dirty_pages_pct variable specifies the target maximum percentage of unwritten (dirty) pages in the buffer pool. If this percentage is exceeded, flushing will take place.

innodb_max_dirty_pages_pct_lwm

The innodb_max_dirty_pages_pct_lwm variable determines the low-water mark percentage of dirty pages that will enable preflushing to lower the dirty page ratio. The default value is `0`.

> **Tip:**
>
> To make flushing more eager and ensure more consistent background I/O, you can set `innodb_max_dirty_pages_pct_lwm` to a very low value, such as `0.001`:
>
> ```
> SET GLOBAL innodb_max_dirty_pages_pct_lwm=0.001;
> ```

Configuring the InnoDB I/O Capacity

increasing the amount of I/O capacity available to InnoDB can help increase the performance of page flushing. The unit of innodb_io_capacity is the number of data pages (of the size defined by `innodb_page_size`) that can be written per second.

Scope of Throttling

It is critical to understand the restricted scope of this variable in modern versions of MariaDB:

- Checkpoint Flushing Only: innodb_io_capacity only throttles checkpoint flushing (background or idle flushing). It does not throttle LRU eviction flushing, which handles the removal of pages when the buffer pool is at capacity.
- Interaction with `innodb_flush_sync`: The `innodb_io_capacity` limit is only effective when innodb_flush_sync is set to `OFF`. When `innodb_flush_sync=ON` (the default), InnoDB may ignore this limit during aggressive "furious flushing" if a log checkpoint is urgently required to prevent the redo log from filling up.

- No Throttling for Buffer Pool Loading: As of MariaDB 10.5.19, 10.6.12, 10.11.2, and later, this parameter no longer throttles the loading of buffer pool dumps at startup (MDEV-25417). Startup loads are now performed at best-effort speed.
- Interaction with innodb_flush_sync: The `innodb_io_capacity` limit is only effective when innodb_flush_sync is set to `OFF`. When `innodb_flush_sync=ON` (the default), InnoDB may ignore this limit during aggressive "furious flushing" if a log checkpoint is urgently required to prevent the redo log from filling up.
- Shared Storage Consideration: If the InnoDB redo log resides on the same physical storage as the data files, ensure you leave some spare capacity for log writes so they are not blocked by background page flushing.

Adjusting I/O Capacity

The amount of I/O capacity available to InnoDB can be configured by setting the innodb_io_capacity system variable. This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_io_capacity=20000;
```

The maximum amount of I/O capacity available to InnoDB in an emergency defaults to either `2000` or twice `innodb_io_capacity`, whichever is higher, or can be directly configured by setting the innodb_io_capacity_max system variable.

Device-Specific Recommendations

When setting these variables, consider the physical limits of your storage hardware:

Storage Device Type	Typical IOPS Capability	Recommended innodb_io_capacity
SATA HDD	~100 – 200	100 – 200
SATA SSD	~50,000 – 100,000	2,000 – 20,000
NVMe SSD	500,000+	20,000 – 80,000+

For high-speed NVMe storage, a sensible value for `innodb_io_capacity` may be as high as 80,000.

Page Flushing Before MariaDB Server 10.5

InnoDB supported multiple partitions and threads to reduce internal mutex contention. These features were rendered unnecessary by architectural improvements—such as splitting the buffer pool mutex and implementing read-write locks for the page hash—and were removed to reduce context-switching overhead:

- innodb_page_cleaners: Previously allowed the use of multiple cleaner threads; it was deprecated and ignored in MariaDB 10.5.1 and removed entirely in MariaDB 10.6.
- innodb_buffer_pool_instances: Partitioned the buffer pool into multiple instances; this was removed in MariaDB 10.5 as the buffer pool now runs as a single instance.
- innodb_mtflush_threads: A Fusion-io specific parameter for multi-threaded flushing, removed in MariaDB 10.3.2.

InnoDB Purge

When a transaction updates a row in an InnoDB table, InnoDB's MVCC implementation keeps old versions of the row in the InnoDB undo log. The old versions are kept at least until all transactions older than the transaction that updated the row are no longer open. At that point, the old versions can be deleted. InnoDB has a purge process that is used to delete these old versions.

InnoDB Purge Threads

In MariaDB, the InnoDB storage engine uses Purge Threads to perform garbage collection in the background. The Purge Threads are related to multi-version concurrency control (MVCC).

The Purge Threads perform garbage collection of various items:

- The Purge Threads perform garbage collection of the InnoDB Undo Log. When a row is updated in the clustered index, InnoDB updates the values in the clustered index, and the old row version is added to the Undo Log. The Purge Threads scan the Undo Log for row versions that are not needed by open transactions and permanently delete them.
- The Purge Threads perform garbage collection of index records. When an indexed column is updated, InnoDB creates a new index record for the updated value in each affected index, and the old index records are delete-marked. When the primary key column is updated, InnoDB creates a new index record for the updated value in every index, and each old index record is delete-marked. The Purge Threads scan for delete-marked index records and permanently delete them.
- The Purge Threads perform garbage collection of freed overflow pages. BLOB, CHAR, TEXT, VARCHAR, VARBINARY, and related types are sometimes stored on overflow pages. When the value on the overflow page is deleted or updated, the overflow page is no longer needed. The Purge Threads delete these freed overflow pages.

Feature Summary

Feature	Detail	Resources
Thread	InnoDB Purge Threads	
Storage Engine	InnoDB	
Purpose		
Quantity	Set by innodb_purge_threads	Configure the InnoDB Purge Threads

Configuring the Purge Threads

The number of purge threads can be set by configuring the innodb_purge_threads system variable. This system variable can be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_purge_threads=8
```

```
SET GLOBAL innodb_purge_threads=8;

SHOW GLOBAL VARIABLES
   LIKE 'innodb_purge_threads';
```

```
+----------------------+-------+
| Variable_name        | Value |
+----------------------+-------+
| innodb_purge_threads | 8     |
+----------------------+-------+
```

Optimizing Purge Performance

Configuring the Purge Batch Size

The purge batch size is defined as the number of InnoDB undo log records that must be written before triggering purge. The purge batch size can be set by configuring the innodb_purge_batch_size system variable. This system variable can be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_purge_batch_size = 50
```

Configuring the Max Purge Lag

If purge operations are lagging on a busy server, then this can be a tough situation to recover from. As a solution, InnoDB allows you to set the max purge lag. The max purge lag is defined as the maximum number of InnoDB undo logs that can be waiting to be purged from the history until InnoDB begins delaying DML statements.

The max purge lag can be set by configuring the innodb_max_purge_lag system variable. This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_max_purge_lag=1000;
```

This system variable can also be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_max_purge_lag = 1000
```

The maximum delay can be set by configuring the innodb_max_purge_lag_delay system variable. This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_max_purge_lag_delay=100;
```

This system variable can also be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_max_purge_lag_delay = 100
```

Configuring the Purge Rollback Segment Truncation Frequency

The purge rollback segment truncation frequency is defined as the number of purge loops that are run before unnecessary rollback segments are truncated. The purge rollback segment truncation frequency can be set by configuring the innodb_purge_rseg_truncate_frequency system variable. This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_purge_rseg_truncate_frequency=64;
```

This system variable can also be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_purge_rseg_truncate_frequency = 64
```

Configuring the Purge Undo Log Truncation

Purge undo log truncation occurs when InnoDB truncates an entire InnoDB undo log tablespace, rather than deleting individual InnoDB undo log records.

Purge undo log truncation can be enabled by configuring the innodb_undo_log_truncate system variable. This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_undo_log_truncate=ON;
```

This system variable can also be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_undo_log_truncate = ON
```

An InnoDB undo log tablespace is truncated when it exceeds the maximum size that is configured for InnoDB undo log tablespaces. The maximum size can be set by configuring the innodb_max_undo_log_size system variable. This system variable can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_max_undo_log_size='64M';
```

This system variable can also be specified as a command-line argument to mariadbd, or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_max_undo_log_size = 64M
```

Purge's Effect on Row Metadata

An InnoDB table's clustered index has three hidden system columns that are automatically generated. These hidden system columns are:

- `DB_ROW_ID` - If the table has no other `PRIMARY KEY` or no other `UNIQUE KEY` defined as `NOT NULL` that can be promoted to the table's `PRIMARY KEY`, then InnoDB will use a hidden system column called `DB_ROW_ID`. InnoDB will automatically generate the value for the column from a global InnoDB-wide 48-bit sequence (instead of being table-local).
- `DB_TRX_ID` - The transaction ID of either the transaction that last changed the row or the transaction that currently has the row locked.
- `DB_ROLL_PTR` - A pointer to the InnoDB undo log that contains the row's previous record. The value of `DB_ROLL_PTR` is only valid if `DB_TRX_ID` belongs to the current read view. The oldest valid read view is the purge view.

If a row's last InnoDB undo log record is purged, this can obviously affect the value of the row's `DB_ROLL_PTR` column, because there would no longer be any InnoDB undo log record for the pointer to reference.

The purge process will set a row's `DB_TRX_ID` column to `0` after all of the row's associated InnoDB undo log records have been deleted. This change allows InnoDB to perform an optimization: if a query wants to read a row,

and if the row's `DB_TRX_ID` column is set to `0`, then it knows that no other transaction has the row locked. Usually, InnoDB needs to lock the transaction system's mutex in order to safely check whether a row is locked, but this optimization allows InnoDB to confirm that the row can be safely read without any heavy internal locking.

This optimization can speed up reads, but it comes at a noticeable cost at other times. For example, it can cause the purge process to use more I/O after inserting a lot of rows, since the value of each row's `DB_TRX_ID` column will have to be reset.

InnoDB Undo Log

Overview

When a transaction writes data, it always inserts them in the table indexes or data (in the buffer pool or in physical files). No private copies are created. The old versions of data being modified by active InnoDB transactions are stored in the undo log. The original data can then be restored, or viewed by a consistent read.

Implementation Details

Before a row is modified, a diff is copied into the undo log. Each normal row contains a pointer to the most recent version of the same row in the undo log. Each row in the undo log contains a pointer to previous version, if any. So, each modified row has a history chain.

Rows are never physically deleted until a transaction ends. If they were deleted, the restore in `ROLLBACK` would be impossible. Thus, rows are simply marked for deletion.

Each transaction uses a *view* of the records. The transaction isolation level determines how this view is created. For example, `READ UNCOMMITTED` usually uses the current version of rows, even if they are not committed (*dirty reads*). Other isolation levels require that the most recent committed version of rows is searched in the undo log. `READ COMMITTED` uses a different view for each table, while `REPEATABLE READ` and `SERIALIZABLE` use the same view for all tables.

There is also a global history list of the data. When a transaction is committed, its history is added to this history list. The order of the list is the chronological order of the commits.

The purge thread deletes the rows in the undo log which are not needed by any existing view. The rows for which a most recent version exists are deleted, as well as the delete-marked rows.

If InnoDB needs to restore an old version, it will simply replace the newer version with the older one. When a transaction inserts a new row, there is no older version. However, in that case, the restore can be done by deleting the inserted rows.

Effects of Long-Running Transactions

Understanding how the undo log works helps with understanding the negative effects long transactions.

- Long transactions generate several old versions of the rows in the undo log. Those rows will probably be needed for a longer time, because other long transactions will need them. Since those transactions will generate more modified rows, a sort of combinatorial explosion can be observed. Thus, the undo log requires more space.
- Transaction may need to read very old versions of the rows in the history list, thus their performance will degrade.

Of course read-only transactions do not write more entries in the undo log; however, they delay the purging of existing entries.

Also, long transactions can more likely result in deadlocks, but this problem is not related to the undo log.

Feature Summary

Feature	Detail	Resources
Transaction Log	InnoDB Undo Log	
Storage Engine	InnoDB	
Purpose	Multi-Version Concurrency Control (MVCC)	
Availability	All ES and CS versions	MariaDB Enterprise Server
Location	By default, located in InnoDB system tablespace When innodb_undo_tablespaces	`innodb_undo_tablespaces` is set, located in directory set by innodb_undo_directory (Defaults to datadir)
Quantity	Set by innodb_undo_tablespaces	Configure the InnoDB Undo Log
Size	10 MB per tablespace by default (grows as needed)	

Configuration

System variables affecting undo logs include:

- innodb_max_undo_log_size
- innodb_undo_directory
- innodb_undo_log_truncate
- innodb_undo_logs
- innodb_undo_tablespaces
- innodb_purge_batch_size
- innodb_purge_rseg_truncate_frequency

The undo log is not a log file that can be viewed on disk in the usual sense, such as the error log or slow query log, but rather an area of storage.

Before MariaDB 11.0, the undo log is usually part of the physical system tablespace, but from MariaDB 10.0, the innodb_undo_directory and innodb_undo_tablespaces system variables can be used to split into different tablespaces and store in a different location (perhaps on a different storage device). From MariaDB 11.0, multiple undo tablespaces are enabled by default, and the innodb_undo_tablespaces default is changed to 3 so that the space occupied by possible bursts of undo log records can be reclaimed after innodb_undo_log_truncate is set.

Each insert or update portion of the undo log is known as a rollback segment. The innodb_undo_logs system variable allowed to reduce the number of rollback segments from the usual 128, to limit the number of concurrently active write transactions. innodb_undo_logs was deprecated and ignored in MariaDB 10.5 and removed in MariaDB 10.6, as it always makes sense to use the maximum number of rollback segments.

The related innodb_available_undo_logs status variable stores the total number of available InnoDB undo logs.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Redo Log

Directly editing or moving the redo logs can cause corruption, and should never normally be attempted.

Overview

The InnoDB storage engine in MariaDB Enterprise Server employs a **Redo Log** to ensure data is written to disk reliably, even in the event of a crash. This is achieved by the Redo Log acting as a transaction log.

Redo Log records are uniquely identified by a **Log Sequence Number (LSN)**. The Redo Log consists of circular log files of a fixed size, where older records are routinely overwritten by newer ones.

InnoDB periodically performs **checkpoints**. During a checkpoint operation, InnoDB writes (flushes) the Redo Log records to the InnoDB tablespace files.

In the event of a server crash, InnoDB utilizes the Redo Log for **crash recovery** during the subsequent server startup. It locates the last checkpoint within the Redo Log and then replays the Redo Log records generated since that checkpoint, effectively flushing these pending changes to the InnoDB tablespace files.

The redo log files are typically named `ib_logfileN`, where `N` is an integer. However, starting with MariaDB 10.5, there is a single redo log file, consistently named `ib_logfile0`. The location of these redo log files is determined by the `innodb_log_group_home_dir` system variable, if configured. If this variable is not set, the redo log files are created in the directory specified by the `datadir` system variable. The redo log plays a crucial role during crash recovery and in the background process of flushing transactions to the tablespaces.

Feature Summary

Feature	Detail	Resources
Transaction Log	InnoDB Redo Log	
Storage Engine	InnoDB	
Purpose	Crash Safety	
Availability	All ES and CS versions	MariaDB Enterprise Server
Location	Set by innodb_log_group_home_dir (Defaults to datadir)	
Quantity	1 (ES 10.5+, CS 10.5+)	Configure the InnoDB Redo Log
Size	Set by innodb_log_file_size (default varies)	Configure the InnoDB Redo Log

Basic Configuration

```
[mariadb]
...
innodb_log_file_size=2G
```

```
SET GLOBAL innodb_log_file_size=(2 * 1024 * 1024 * 1024);

SHOW GLOBAL VARIABLES
   LIKE 'innodb_log_file_size';
```

```
+----------------------+------------+
| Variable_name        | Value      |
+----------------------+------------+
| innodb_log_file_size | 2147483648 |
+----------------------+------------+
```

Flushing Effects on Performance and Consistency

The innodb_flush_log_at_trx_commit system variable determines how often the transactions are flushed to the redo log, and it is important to achieve a good balance between speed and reliability.

Binary Log Group Commit and Redo Log Flushing

When both innodb_flush_log_at_trx_commit=1 (the default) is set and the binary log is enabled, there is one less sync to disk inside InnoDB during commit (2 syncs shared between a group of transactions instead of 3). See Binary Log Group Commit and InnoDB Flushing Performance for more information.

Redo Log Group Capacity

The redo log group capacity is the total combined size of all InnoDB redo logs. The relevant factors are:

- From MariaDB 10.5, there is 1 redo log.
- The size of each redo log file is configured by the innodb_log_file_size system variable. This can safely be set to a much higher value from MariaDB 10.5. Before MariaDB 10.9, resizing required the server to be restarted. From MariaDB 10.9 the variable can be set dynamically.

The redo log group capacity is determined by the following calculation:

`innodb_log_group_capacity` = innodb_log_file_size * innodb_log_files_in_group

For example, if innodb_log_file_size is set to `2G` and innodb_log_files_in_group is set to `2`, then we would have the following:

- `innodb_log_group_capacity` = innodb_log_file_size * innodb_log_files_in_group
- = `2G` * `2`
- = `4G`

Changing the Redo Log Group Capacity

MariaDB starting with 10.5

The number of redo log files is fixed.

The size of redo log files can be changed with the following process:

- Stop the server.
- To change the log file size, configure innodb_log_file_size.
- Start the server.

Log Sequence Number (LSN)

Records within the InnoDB redo log are identified via a log sequence number (LSN).

Checkpoints

When InnoDB performs a checkpoint, it writes the LSN of the oldest dirty page in the InnoDB buffer pool to the InnoDB redo log. If a page is the oldest dirty page in the InnoDB buffer pool, then that means that all pages with lower LSNs have been flushed to the physical InnoDB tablespace files. If the server were to crash, then InnoDB would perform crash recovery by only applying log records with LSNs that are greater than or equal to the LSN of the oldest dirty page written in the last checkpoint.

Checkpoints are one of the tasks performed by the InnoDB master background thread. This thread schedules checkpoints 7 seconds apart when the server is very active, but checkpoints can happen more frequently when the server is less active.

Dirty pages are not actually flushed from the buffer pool to the physical InnoDB tablespace files during a checkpoint. That process happens asynchronously on a continuous basis by InnoDB's write I/O background threads configured by the innodb_write_io_threads system variable. If you want to make this process more aggressive, then you can decrease the value of the innodb_max_dirty_pages_pct system variable. You may also need to better tune InnoDB's I/O capacity on your system by setting the innodb_io_capacity system variable.

Determining the Checkpoint Age

The checkpoint age is the amount of data written to the InnoDB redo log since the last checkpoint.

Determining the Checkpoint Age in InnoDB

MariaDB starting with 10.5

MariaDB 10.5 reintroduced the Innodb_checkpoint_age status variable for determining the checkpoint age.

The checkpoint age can also be determined by the process shown below.

To determine the InnoDB checkpoint age, do the following:

- Query SHOW ENGINE INNODB STATUS.
- Find the `LOG` section:

```
---
LOG
---
Log sequence number 252794398789379
Log flushed up to 252794398789379
Pages flushed up to 252792767756840
Last checkpoint at 252792767756840
0 pending log flushes, 0 pending chkp writes
23930412 log i/o's done, 2.03 log i/o's/second
```

- Perform the following calculation:

`innodb_checkpoint_age` = `Log sequence number` - `Last checkpoint at`

In the example above, that would be:

- `innodb_checkpoint_age` = `Log sequence number` - `Last checkpoint at`
- = 252794398789379 - 252792767756840
- = 1631032539 bytes
- = 1631032539 byes / (1024 * 1024 * 1024) (GB/bytes)
- = 1.5 GB of redo log written since last checkpoint

Determining the Redo Log Occupancy

The redo log occupancy is the percentage of the InnoDB redo log capacity that is taken up by dirty pages that have not yet been flushed to the physical InnoDB tablespace files in a checkpoint. Therefore, it's determined by the following calculation:

`innodb_log_occupancy` = innodb_checkpoint_age / innodb_log_group_capacity

For example, if innodb_checkpoint_age is `1.5G` and innodb_log_group_capacity is `4G`, then we would have the following:

- `innodb_log_occupancy` = innodb_checkpoint_age / innodb_log_group_capacity
- = `1.5G` / `4G`
- = `0.375`

If the calculated value for redo log occupancy is too close to `1.0`, then the InnoDB redo log capacity may be too small for the current workload.

MariaDB 10.8 Updates

A number of redo log improvements were made in MariaDB 10.8:

- Autosize innodb_buffer_pool_chunk_size (MDEV-25342).
- Improve the redo log for concurrency (MDEV-14425).
- Remove FIL_PAGE_FILE_FLUSH_LSN (MDEV-27199).

Before MariaDB 10.8.1, mariadb-backup –prepare created a zero-length ib_logfile0 as a dummy placeholder. From MariaDB 10.8.1 (MDEV-14425), the size of that dummy file was increased to 12304 (0x3010) bytes, and all updates of FIL_PAGE_FILE_FLUSH_LSN in the first page of the system tablespace are removed.

From MariaDB 10.8.1, if the server is started up with a zero-sized ib_logfile0, it is assumed that an upgrade is being performed after a backup had been prepared. The start LSN will then be read from FIL_PAGE_FILE_FLUSH_LSN, and a new log file are created starting from exactly that LSN.

Manually creating a zero-sized ib_logfile0 without manually updating the FIL_PAGE_FILE_FLUSH_LSN in the system tablespace to a recent enough LSN may result in error messages such as “page LSN is in the future”. If a log was discarded while some changes had already been written to data pages, all sort of corruption may occur.

If the database was initialized with a server that never updates the FIL_PAGE_FILE_FLUSH_LSN field, then any server startup attempts with a zero-size ib_logfile0 are refused because of an invalid LSN. If that field was ever updated with a valid LSN by an older server, this safety mechanism cannot work, and the server may “rewind” to an earlier LSN.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Strict Mode

InnoDB strict mode is similar to SQL strict mode. When it is enabled, certain InnoDB warnings become errors instead.

Configuring InnoDB Strict Mode

InnoDB strict mode is enabled by default.

InnoDB strict mode can be enabled or disabled by configuring the innodb_strict_mode server system variable.

Its global value can be changed dynamically with SET GLOBAL:

```
SET GLOBAL innodb_strict_mode=ON;
```

Its value for the current session can also be changed dynamically with SET SESSION:

```
SET SESSION innodb_strict_mode=ON;
```

It can also be set in a server option group in an option file prior to starting up the server:

```
[mariadb]
...
innodb_strict_mode=ON
```

InnoDB Strict Mode Errors

Wrong Create Options

If InnoDB strict mode is enabled, and if a DDL statement is executed and invalid or conflicting table options are specified, then an error is raised. The error will only be a generic error that says the following:

```
ERROR 1005 (HY000): Can't create table `db1`.`tab` (errno: 140 "Wrong create options")
```

However, more details about the error can be found by executing SHOW WARNINGS.

For example, the error is raised in the following cases:

- The KEY_BLOCK_SIZE table option is set to a non-zero value, but the ROW_FORMAT table option is set to some row format other than the COMPRESSED row format:

```
SET SESSION innodb_strict_mode=ON;

CREATE OR REPLACE TABLE tab (
   id INT PRIMARY KEY,
   str VARCHAR(50)
)
KEY_BLOCK_SIZE=4
ROW_FORMAT=DYNAMIC;
ERROR 1005 (HY000): Can't create table `db1`.`tab` (errno: 140 "Wrong create options")

SHOW WARNINGS;
+---------+------+-----------------------------------------------------------------------+

COMPRESSED Row Format

If InnoDB strict mode is enabled, and if a table uses the COMPRESSED row format, and if the table's KEY_BLOCK_SIZE is too small to contain a row, then an error is returned by the statement.

Row Size Too Large

If InnoDB strict mode is enabled, and if a table exceeds its row format's maximum row size, then InnoDB will return an error.

```
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT OR BLOB may help. IN current row format, BLOB prefix of 0 bytes IS stored inline.
```

See Troubleshooting Row Size Too Large Errors with InnoDB for more information.

InnoDB System Variables

This page documents system variables related to the InnoDB storage engine. For options that are not system variables, see InnoDB Options.

See Server System Variables for a complete list of system variables and instructions on setting them.

Also see the Full list of MariaDB options, system and status variables.

`have_innodb`

- Description: If the server supports InnoDB tables, are set to `YES`, otherwise are set to `NO`. Removed in MariaDB 10.0, use the Information Schema PLUGINS table or SHOW ENGINES instead.
- Scope: Global
- Dynamic: No
- Removed: MariaDB 10.0

`ignore_builtin_innodb`

- Description: Setting this to `1` results in the built-in InnoDB storage engine being ignored. In some versions of MariaDB, XtraDB is the default and is always present, so this variable is ignored and setting it results in a warning. From MariaDB 10.0.1 to MariaDB 10.0.8, when InnoDB was the default instead of XtraDB, this variable needed to be set. Usually used in conjunction with the plugin-load=innodb=ha_innodb option to use the InnoDB plugin.
- Command line: `--ignore-builtin-innodb`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_adaptive_checkpoint`

- Description: Replaced with innodb_adaptive_flushing_method. Controls adaptive checkpointing. InnoDB's fuzzy checkpointing can cause stalls, as many dirty blocks are flushed at once as the checkpoint age nears the maximum. Adaptive checkpointing aims for more consistent flushing, approximately `modified age / maximum checkpoint age`. Can result in larger transaction log files
  - `reflex` Similar to innodb_max_dirty_pages_pct flushing but flushes blocks constantly and contiguously based on the oldest modified age. If the age exceeds 1/2 of the maximum age capacity, flushing are weak

contiguous. If the age exceeds 3/4, flushing are strong. Strength can be adjusted by the variable innodb_io_capacity.
    - `estimate` The default, and independent of innodb_io_capacity. If the oldest modified age exceeds 1/2 of the maximum age capacity, blocks are flushed every second at a rate determined by the number of modified blocks, LSN progress speed and the average age of all modified blocks.
    - `keep_average` Attempts to keep the I/O rate constant by using a shorter loop cycle of one tenth of a second. Designed for SSD cards.

- Command line: `--innodb-adaptive-checkpoint=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`
- Default Value: `estimate`
- Valid Values: `none` or `0`, `reflex` or `1`, `estimate` or `2`, `keep_average` or `3`
- Removed: XtraDB 5.5 - replaced with innodb_adaptive_flushing_method

`innodb_adaptive_flushing`

- Description: If set to `1`, the default, the server will dynamically adjust the flush rate of dirty pages in the InnoDB buffer pool. This assists to reduce brief bursts of I/O activity. If set to `0`, adaptive flushing will only take place when the limit specified by innodb_adaptive_flushing_lwm is reached.
- Command line: `--innodb-adaptive-flushing={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_adaptive_flushing_lwm`

- Description: Adaptive flushing is enabled when this low water mark percentage of the InnoDB redo log capacity is reached. Takes effect even if innodb_adaptive_flushing is disabled.
- Command line: `--innodb-adaptive-flushing-lwm=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `double`
- Default Value: `10.000000`
- Range: `0` to `70`

`innodb_adaptive_flushing_method`

- Description: Determines the method of flushing dirty blocks from the InnoDB buffer pool. If set to `native` or `0`, the original InnoDB method is used. The maximum checkpoint age is determined by the total length of all transaction log files. When the checkpoint age reaches the maximum checkpoint age, blocks are flushed. This can cause lag if there are many updates per second and many blocks with an almost identical age need to be flushed. If set to `estimate` or `1`, the default, the oldest modified age are compared with the maximum age capacity. If it's more than 1/4 of this age, blocks are flushed every second. The number of blocks flushed is determined by the number of modified blocks, the LSN progress speed and the average age of all modified blocks. It's therefore independent of the innodb_io_capacity for the 1-second loop, but not entirely so for the 10-second loop. If set to `keep_average` or `2`, designed specifically for SSD cards, a shorter loop cycle is used in

an attempt to keep the I/O rate constant. Removed in MariaDB 10.0/XtraDB 5.6 and replaced with InnoDB flushing method from MySQL 5.6.

- Command line: `innodb-adaptive-flushing-method=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `estimate`
- Valid Values: `native` or `0`, `estimate` or `1`, `keep_average` or `2`
- Removed: MariaDB 10.0 - replaced with InnoDB flushing method from MySQL 5.6

`innodb_adaptive_hash_index`

- Description: If set to `1`, the default until MariaDB 10.5, the InnoDB hash index is enabled. Based on performance testing (MDEV-17492), the InnoDB adaptive hash index helps performance in mostly read-only workloads, and could slow down performance in other environments, especially DROP TABLE, TRUNCATE TABLE, ALTER TABLE, or DROP INDEX operations. From MariaDB 13.1.1, this variable is an enumeration. The `IF_SPECIFIED` value enables the adaptive hash index only for tables and indexes whose ADAPTIVE_HASH_INDEX option is set to `YES`.
- Command line: `--innodb-adaptive-hash-index[={OFF|ON|IF_SPECIFIED}]`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration` (`boolean` before MariaDB 13.1.1)
- Valid Values: `OFF`, `ON`, `IF_SPECIFIED` (from MariaDB 13.1.1)
- Default Value: `OFF` (>= MariaDB 10.5), `ON` (<= MariaDB 10.4)

`innodb_adaptive_hash_index_cells`

- Description: Further improves the performance of the InnoDB adaptive hash index (AHI) when `innodb_adaptive_hash_index` is enabled. This variable allows for manual configuration of the hash table size to resolve contention on the `btr_sea::partition::latch` during high-concurrency workloads. The specified value is effectively multiplied by the number of partitions defined in `innodb_adaptive_hash_index_parts`, as each partition maintains its own hash table. Increasing this value can reduce the length of hash bucket chains, which helps avoid performance “hiccups” and “avalanche effects” caused by multiple threads spinning for AHI lookups.
- Command line: `--innodb-adaptive-hash-index-cells=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `134217728`
- Introduced: MariaDB 11.8.4, MariaDB 12.1.2, MariaDB 12.2.1

`innodb_adaptive_hash_index_partitions`

- Description: Specifies the number of partitions for use in adaptive searching. If set to `1`, no extra partitions are created. XtraDB-only. From MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB), this is an alias for innodb_adaptive_hash_index_parts to allow for easier upgrades.
- Command line: `innodb-adaptive-hash-index-partitions=#`
- Scope: Global
- Dynamic: No

- Data Type: `numeric`
- Default Value: `1`
- Range: `1` to `64`

`innodb_adaptive_hash_index_parts`

- Description: Specifies the number of partitions for use in adaptive searching. If set to `1`, no extra partitions are created.
- Command line: `innodb-adaptive-hash-index-parts=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `8`
- Range: `1` to `512`

`innodb_adaptive_max_sleep_delay`

- Description: Maximum time in microseconds to automatically adjust the innodb_thread_sleep_delay value to, based on the workload. Useful in extremely busy systems with hundreds of thousands of simultaneous connections. `0` disables any limit. Deprecated and ignored from MariaDB 10.5.5.
- Command line: `--innodb-adaptive-max-sleep-delay=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `0` (>= MariaDB 10.5.5)
  - `150000` (<= MariaDB 10.5.4)
- Range: `0` to `1000000`
- Introduced: MariaDB 10.0
- Deprecated: MariaDB 10.5.5
- Removed: MariaDB 10.6.0

`innodb_additional_mem_pool_size`

- Description: Size in bytes of the InnoDB memory pool used for storing information about internal data structures. Defaults to 8MB, if your application has many tables and a large structure, and this is exceeded, operating system memory are allocated and warning messages written to the error log, in which case you should increase this value. Deprecated in MariaDB 10.0 and removed in MariaDB 10.2 along with InnoDB's internal memory allocator.
- Command line: `--innodb-additional-mem-pool-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `8388608`
- Range: `2097152` to `4294967295`
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.2.2

`innodb_alter_copy_bulk`

- Description: Allow bulk insert operation for copy alter operation.
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`
- Introduced: MariaDB 10.11.9, MariaDB 11.1.6, MariaDB 11.2.5, MariaDB 11.4.3, MariaDB 11.5.2, MariaDB 11.6.1

`innodb_api_bk_commit_interval`

- Description: Time in seconds between auto-commits for idle connections using the InnoDB memcached interface (not implemented in MariaDB).
- Command line: `--innodb-api-bk-commit-interval=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `5`
- Range: `1` to `1073741824`
- Introduced: MariaDB 10.0
- Removed: MariaDB 10.2.4

`innodb_api_disable_rowlock`

- Description: For use with MySQL's memcached (not implemented in MariaDB)
- Command line: `--innodb-api-disable-rowlock={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.0
- Removed: MariaDB 10.2.4

`innodb_api_enable_binlog`

- Description: For use with MySQL's memcached (not implemented in MariaDB)
- Command line: `--innodb-api-enable-binlog={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.0
- Removed: MariaDB 10.2.4

`innodb_api_enable_mdl`

- Description: For use with MySQL's memcached (not implemented in MariaDB)
- Command line: `--innodb-api-enable-mdl={0|1}`
- Scope: Global
- Dynamic: No

- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.0
- Removed: MariaDB 10.2.4

`innodb_api_trx_level`

- Description: For use with MySQL's memcached (not implemented in MariaDB)
- Command line: `--innodb-api-trx-level=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Introduced: MariaDB 10.0
- Removed: MariaDB 10.2.4

`innodb_auto_lru_dump`

- Description: Renamed innodb_buffer_pool_restore_at_startup since XtraDB 5.5.10-20.1, which was in turn replaced by innodb_buffer_pool_load_at_startup in MariaDB 10.0.
- Command line: `--innodb-auto-lru-dump=#`
- Removed: XtraDB 5.5.10-20.1

`innodb_autoextend_increment`

- Description: Size in MB to increment an auto-extending shared tablespace file when it becomes full. If innodb_file_per_table was set to `1`, this setting does not apply to the resulting per-table tablespace files, which are automatically extended in their own way.
- Command line: `--innodb-autoextend-increment=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `64` (from MariaDB 10.0) `8` (before MariaDB 10.0),
- Range: `1` to `1000`

`innodb_autoinc_lock_mode`

- Description: The lock mode that is used when generating AUTO_INCREMENT values for InnoDB tables.
  - Valid values are:
    - `0` is the traditional lock mode.
    - `1` is the consecutive lock mode.
    - `2` is the interleaved lock mode.
  - In order to use Galera Cluster, the lock mode needs to be set to `2`.
  - See AUTO_INCREMENT Handling in InnoDB: AUTO_INCREMENT Lock Modes for more information.
- Command line: `--innodb-autoinc-lock-mode=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `1`

- Range: `0` to `2`

`innodb_background_scrub_data_check_interval`

- Description: Check if spaces needs scrubbing every innodb_background_scrub_data_check_interval seconds. See Data Scrubbing. Deprecated and ignored from MariaDB 10.5.2.
- Command line: `--innodb-background-scrub-data-check-interval=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `3600`
- Range: `1` to `4294967295`
- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_background_scrub_data_compressed`

- Description: Enable scrubbing of compressed data by background threads (same as encryption_threads). See Data Scrubbing. Deprecated and ignored from MariaDB 10.5.2.
- Command line: `--innodb-background-scrub-data-compressed={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `0`
- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_background_scrub_data_interval`

- Description: Scrub spaces that were last scrubbed longer than this number of seconds ago. See Data Scrubbing. Deprecated and ignored from MariaDB 10.5.2.
- Command line: `--innodb-background-scrub-data-interval=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `604800`
- Range: `1` to `4294967295`
- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_background_scrub_data_uncompressed`

- Description: Enable scrubbing of uncompressed data by background threads (same as encryption_threads). See Data Scrubbing. Deprecated and ignored from MariaDB 10.5.2.
- Command line: `--innodb-background-scrub-data-uncompressed={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `0`

- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_blocking_buffer_pool_restore`

- Description: If set to `1` (`0` is default), XtraDB will wait until the least-recently used (LRU) dump is completely restored upon restart before reporting back to the server that it has successfully started up. Available with XtraDB only, not InnoDB.
- Command line: `innodb-blocking-buffer-pool-restore={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.0.0

`innodb_buf_dump_status_frequency`

- Description: Determines how often (as a percent) the buffer pool dump status should be printed in the logs. For example, `10` means that the buffer pool dump status is printed when every 10% of the number of buffer pool pages are dumped. The default is `0` (only start and end status is printed).
- Command line: `--innodb-buf-dump-status-frequency=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `100`

`innodb_buffer_pool_chunk_size`

- Description: Chunk size used for dynamically resizing the buffer pool. Note that changing this setting can change the size of the buffer pool. When large-pages is used this value is effectively rounded up to the next multiple of large-page-size. See Setting Innodb Buffer Pool Size Dynamically. From MariaDB 10.8.0, the variable is autosized based on the buffer pool size.
- Command line: `--innodb-buffer-pool-chunk-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value:
  - `autosize (0)`, resulting in innodb_buffer_pool_size/64, if large_pages round down to multiple of largest page size, with 1MiB minimum (from MariaDB 10.8.1)
  - `134217728` (until MariaDB 10.8.0)
- Range:
  - `0`, as autosize, and then `1048576` to `18446744073709551615` (from MariaDB 10.8)
  - `1048576` to innodb_buffer_pool_size/innodb_buffer_pool_instances (until MariaDB 10.7)
- Block size: `1048576`
- Deprecated and ignored from MariaDB 10.11.12, MariaDB 11.4.6, MariaDB 11.8.2

`innodb_buffer_pool_dump_at_shutdown`

- Description: Whether to record pages cached in the buffer pool on server shutdown, which reduces the length of the warmup the next time the server starts. The related innodb_buffer_pool_load_at_startup specifies whether the buffer pool is automatically warmed up at startup.
- Command line: `--innodb-buffer-pool-dump-at-shutdown={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_buffer_pool_dump_now`

- Description: Immediately records pages stored in the buffer pool. The related innodb_buffer_pool_load_now does the reverse, and will immediately warm up the buffer pool.
- Command line: `--innodb-buffer-pool-dump-now={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.0

`innodb_buffer_pool_dump_pct`

- Description: Dump only the hottest N% of each buffer pool.
- Command line: `--innodb-buffer-pool-dump-pct={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value:
  - `25`
- Range: `1` to `100`

`innodb_buffer_pool_evict`

- Description: Evict pages from the buffer pool. If set to “uncompressed” then all uncompressed pages are evicted from the buffer pool. Variable to be used only for testing. Only exists in DEBUG builds.
- Command line: `--innodb-buffer-pool-evict=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`
- Default Value: `""`
- Valid Values: “” or “uncompressed”

`innodb_buffer_pool_filename`

- Description: The file that holds the buffer pool list of page numbers set by innodb_buffer_pool_dump_at_shutdown and innodb_buffer_pool_dump_now.
- Command line: `--innodb-buffer-pool-filename=file`
- Scope: Global

- Dynamic: No
- Data Type: `string`
- Default Value: `ib_buffer_pool`
- Introduced: MariaDB 10.0

`innodb_buffer_pool_instances`

- Description: If innodb_buffer_pool_size is set to more than 1GB, innodb_buffer_pool_instances divides the InnoDB buffer pool into the specified number of instances. The default was 1 in MariaDB 5.5, but for large systems with buffer pools of many gigabytes, many instances could help reduce contention concurrency through MariaDB 10.2. The default is 8 in MariaDB 10 (except on Windows 32-bit, where it varies according to innodb_buffer_pool_size, or from MariaDB 10.2.2, where it is set to 1 if innodb_buffer_pool_size < 1GB). Each instance manages its own data structures and takes an equal portion of the total buffer pool size, so for example if innodb_buffer_pool_size is 4GB and `innodb_buffer_pool_instances` is set to 4, each instance are 1GB. Each instance should ideally be at least 1GB in size.
  Starting with MariaDB 10.3, performance improvements intended to reduce the overhead of context-switching between buffer pools changed the recommended number of innodb_buffer_pool_instances to one for every 128GB of buffer pool size. Based on these changes, the variable is deprecated and ignored from MariaDB 10.5.1, where the buffer pool runs in a single instance regardless of size.
- Command line: `--innodb-buffer-pool-instances=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: >= MariaDB 10.0.4: `8`, `1` (>= MariaDB 10.2.2 if innodb_buffer_pool_size < 1GB), or dependent on innodb_buffer_pool_size (Windows 32-bit)
- Deprecated: MariaDB 10.5.1
- Removed: MariaDB 10.6.0

`innodb_buffer_pool_load_abort`

- Description: Aborts the process of restoring buffer pool contents started by innodb_buffer_pool_load_at_startup or innodb_buffer_pool_load_now.
- Command line: `--innodb-buffer-pool-load-abort={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_buffer_pool_load_at_startup`

- Description: Specifies whether the buffer pool is automatically warmed up when the server starts by loading the pages held earlier. The related innodb_buffer_pool_dump_at_shutdown specifies whether pages are saved at shutdown. If the buffer pool is large and taking a long time to load, increasing innodb_io_capacity at startup may help.
- Command line: `--innodb-buffer-pool-load-at-startup={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`

`innodb_buffer_pool_load_now`

- Description: Immediately warms up the buffer pool by loading the stored data pages. The related innodb_buffer_pool_dump_now does the reverse, and immediately records pages stored in the buffer pool.
- Command line: `--innodb-buffer-pool-load-now={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_buffer_pool_load_pages_abort`

- Description: Number of pages during a buffer pool load to process before signaling innodb_buffer_pool_load_abort=1. Debug builds only.
- Command line: `--innodb-buffer-pool-load-pages-abort=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `9223372036854775807`
- Range: `1` to `9223372036854775807`

`innodb_buffer_pool_populate`

- Description: When set to `1` (`0` is default), XtraDB will preallocate pages in the buffer pool on starting up so that NUMA[9] allocation decisions are made while the buffer cache is still clean. XtraDB only. This option was made ineffective in MariaDB 10.0.23. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-buffer-pool-populate={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.0.23
- Removed: MariaDB 10.3.0

`innodb_buffer_pool_restore_at_startup`

- Description: Time in seconds between automatic buffer pool dumps. If set to a non-zero value, XtraDB will also perform an automatic restore of the buffer pool at startup. If set to `0`, automatic dumps are not performed, nor automatic restores on startup. Replaced by innodb_buffer_pool_load_at_startup in MariaDB 10.0.
- Command line: `innodb-buffer-pool-restore-at-startup`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range - 32 bit: `0` to `4294967295`
- Range - 64 bit: `0` to `18446744073709547520`
- Removed: MariaDB 10.0 - replaced by innodb_buffer_pool_load_at_startup

`innodb_buffer_pool_shm_checksum`

- Description: Used with Percona's SHM buffer pool patch in XtraDB 5.5. Was shortly deprecated and removed in XtraDB 5.6. XtraDB only.
- Command line: `innodb-buffer-pool-shm-checksum={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`
- Removed: MariaDB 10.0

`innodb_buffer_pool_shm_key`

- Description: Used with Percona's SHM buffer pool patch in XtraDB 5.5. Later deprecated in XtraDB 5.5, and removed in XtraDB 5.6.
- Command line: `innodb-buffer-pool-shm-key={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `0`
- Removed: MariaDB 10.0

`innodb_buffer_pool_size`

- Description: InnoDB buffer pool size in bytes. The primary value to adjust on a database server with entirely/primarily InnoDB tables, can be set up to 80% of the total memory in these environments. See the InnoDB Buffer Pool for more on setting this variable, and also Setting InnoDB Buffer Pool Size Dynamically if doing so dynamically.
- Command line: `--innodb-buffer-pool-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `134217728` (128MiB)
- Range:
  - Minimum: `5242880` (5MiB) for InnoDB Page Size <= 16k otherwise `25165824` (24MiB) for InnoDB Page Size > 16k (for versions less than next line)
  - Minimum: `2MiB` InnoDB Page Size = 4k, `3MiB` InnoDB Page Size = 8k, `5MiB` InnoDB Page Size = 16k, `10MiB` InnoDB Page Size = 32k, `20MiB` InnoDB Page Size = 64k, (>= MariaDB 10.2.42, >= MariaDB 10.3.33, >= MariaDB 10.4.23, >= MariaDB 10.5.14, >= MariaDB 10.6.6, >= MariaDB 10.7.2)
  - Minimum: 1GiB for innodb_buffer_pool_instances > 1 (<= MariaDB 10.7)
  - Maximum: `9223372036854775807` (8192PB) (all versions)
- Block size: `1048576`

`innodb_buffer_pool_size_auto_min`

- Description: Minimum `innodb_buffer_pool_size` in bytes for dynamic shrinking on memory pressure. Only affects Linux. If a memory pressure event is reported by Linux, the `innodb_buffer_pool_size` may be automatically shrunk towards this value. By default, set to `innodb_buffer_pool_size_max`, that is, memory pressure events will be ignored. `0` sets no minimum value.
- Command line: `--innodb-buffer-pool-size-auto-min=#`

- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `134217728` (128MiB)
- Range: `0` to `18446744073701163008`
- Block size: `8388608` (8 MB on 64-bit systems)
- Introduced: MariaDB 10.11.12, MariaDB 11.4.6, MariaDB 11.8.2

`innodb_buffer_pool_size_max`

> **Important:**
>
> `innodb_buffer_pool_size_max` is a **read-only** variable. If not specified at startup, it defaults to the initial `innodb_buffer_pool_size`, which effectively disables upward dynamic resizing at runtime (attempts to increase size results in *Warning 1292*).

> **Warning:**
>
> Automatic upward dynamic resizing is not yet implemented (MDEV-36197). This variable currently serves only as a pre-allocated virtual address ceiling for **manual** resizing operations.

- Description: Maximum `innodb_buffer_pool_size` value. On 64-bit systems other than IBM AIX, the default is 8 TiB, and the minimum 8 MiB. On other systems, the default and minimum are `0`, and the value `0` is replaced with the initial `innodb_buffer_pool_size` rounded up to the allocation unit (2 MiB or 8 MiB). The maximum value is 4GiB-2MiB on 32-bit systems and 16EiB-8MiB on 64-bit systems. This maximum is likely to be limited further by the operating system.
  On 64-bit systems, while the default maximum is 8 TiB, the actual available address space may be restricted by operating system limits (such as `RLIMIT_AS` [10]) or specific hardware architectures. If MariaDB is unable to allocate the default 8 TiB of virtual address space at startup, it automatically attempts to fall back to a 128 GiB limit to ensure the server can still start. (128 GiB is often chosen as a fallback because it's a safe value that almost any modern 64-bit Linux kernel/CPU can handle without special configuration, while still being plenty large for the vast majority of database workloads.)
- Command line: `--innodb-buffer-pool-size-max=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: specified by the initial value of innodb_buffer_pool_size, rounded up to the block size of that variable. See the section about buffer pool changes in MariaDB 10.11.12, 11.4.6, and 11.8.2.
- Range: `0` to `18446744073701163008`
- Block size: `8388608` (8 MB on 64-bit systems)
- Introduced: MariaDB 10.11.12, MariaDB 11.4.6, MariaDB 11.8.2

`innodb_change_buffer_dump`

- Description: If set, causes the contents of the InnoDB change buffer to be dumped to the server error log at startup. Only available in debug builds.
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`

- Introduced: MariaDB 10.2.28, MariaDB 10.3.19, MariaDB 10.4.9

`innodb_change_buffer_max_size`

- Description: Maximum size of the InnoDB Change Buffer as a percentage of the total buffer pool. The default is 25%, and this can be increased up to 50% for servers with high write activity, and lowered down to 0 for servers used exclusively for reporting.
- Command line: `--innodb-change-buffer-max-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `25`
- Range: `0` to `50`
- Introduced: MariaDB 10.0
- Deprecated: MariaDB 10.9.0
- Removed: MariaDB 11.0.0

`innodb_change_buffering`

- Description: Sets how InnoDB change buffering is performed. See InnoDB Change Buffering for details on the settings. Deprecated and ignored from MariaDB 10.9.0.
- Command line: `--innodb-change-buffering=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration` (>= MariaDB 10.3.7), `string` (<= MariaDB 10.3.6)
- Default Value:
  - = MariaDB 10.5.15, MariaDB 10.6.7, MariaDB 10.7.3, MariaDB 10.8.2: `none`
  - <= MariaDB 10.5.14, MariaDB 10.6.6, MariaDB 10.7.2, MariaDB 10.8.1: `all`
- Valid Values: `inserts`, `none`, `deletes`, `purges`, `changes`, `all`
- Deprecated: MariaDB 10.9.0
- Removed: MariaDB 11.0.0

`innodb_change_buffering_debug`

- Description: If set to `1`, an InnoDB Change Buffering debug flag is set. `1` forces all changes to the change buffer, while `2` causes a crash at merge. `0`, the default, indicates no flag is set. Only available in debug builds.
- Command line: `--innodb-change-buffering-debug=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `2`

`innodb_checkpoint_age_target`

- Description: The maximum value of the checkpoint age. If set to `0`, has no effect. Removed in MariaDB 10.0/XtraDB 5.6 and replaced with InnoDB flushing method from MySQL 5.6.
- Command line: `innodb-checkpoint-age-target=#`

- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` upwards
- Removed: MariaDB 10.0 - replaced with InnoDB flushing method from MySQL 5.6.

`innodb_checksum_algorithm`

- Description: Specifies how the InnoDB tablespace checksum is generated and verified.
  - `innodb`: Backwards compatible with earlier versions (<= MariaDB 5.5). Deprecated in MariaDB 10.3.29, MariaDB 10.4.19, MariaDB 10.5.10 and removed in MariaDB 10.6. If really needed, data files can still be converted with innochecksum.
  - `crc32`: A newer, faster algorithm, but incompatible with earlier versions. Tablespace blocks are converted to the new format over time, meaning that a mix of checksums may be present.
  - `full_crc32` and `strict_full_crc32`: From MariaDB 10.4.3. Permits encryption to be supported over a SPATIAL INDEX, which `crc32` does not support. Newly-created data files will carry a flag that indicates that all pages of the file will use a full CRC-32C checksum over the entire page contents (excluding the bytes where the checksum is stored, at the very end of the page). Such files will always use that checksum, no matter what parameter `innodb_checksum_algorithm` is assigned to. Even if `innodb_checksum_algorithm` is modified later, the same checksum will continue to be used. A special flag are set in the FSP_SPACE_FLAGS in the first data page to indicate the new format of checksum and encryption/page_compressed. ROW_FORMAT=COMPRESSED tables will only use the old format. These tables do not support new features, such as larger innodb_page_size or instant ADD/DROP COLUMN. Also cleans up the MariaDB tablespace flags - flags are reserved to store the page_compressed compression algorithm, and to store the compressed payload length, so that checksum can be computed over the compressed (and possibly encrypted) stream and can be validated without decrypting or decompressing the page. In the full_crc32 format, there no longer are separate before-encryption and after-encryption checksums for pages. The single checksum is computed on the page contents that is written to the file.See MDEV-12026 for details.
  - `none`: Writes a constant rather than calculate a checksum. Deprecated in MariaDB 10.3.29, MariaDB 10.4.19, MariaDB 10.5.10 and removed in MariaDB 10.6 as was mostly used to disable the original, slow, page checksum for benchmarking purposes.
  - `strict_crc32`, `strict_innodb` and `strict_none`: The options are the same as the regular options, but InnoDB will halt if it comes across a mix of checksum values. These are faster, as both new and old checksum values are not required, but can only be used when setting up tablespaces for the first time.
- Command line: `--innodb-checksum-algorithm=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value:
  - `full_crc32` (>= MariaDB 10.5.0)
  - `crc32` (>= MariaDB 10.2.2 to <= MariaDB 10.4)
  - `innodb` (<= MariaDB 10.2.1)
- Valid Values:
  - > = MariaDB 10.6.0: `crc32`, `full_crc32`, `strict_crc32`, `strict_full_crc32`

    - MariaDB 10.5, >= MariaDB 10.4.3: `innodb`, `crc32`, `full_crc32`, `none`, `strict_innodb`, `strict_crc32`, `strict_none`, `strict_full_crc32`
    - <= MariaDB 10.4.2: `innodb`, `crc32`, `none`, `strict_innodb`, `strict_crc32`, `strict_none`

`innodb_checksums`

- Description: By default, InnoDB performs checksum validation on all pages read from disk, which provides extra fault tolerance. You would usually want this set to `1` in production environments, although setting it to `0` can provide marginal performance improvements. Deprecated and functionality replaced by innodb_checksum_algorithm in MariaDB 10.0, and should be removed to avoid conflicts. `ON` is equivalent to `--innodb_checksum_algorithm=innodb` and `OFF` to `--innodb_checksum_algorithm=none`.
- Command line: `--innodb-checksums`, `--skip-innodb-checksums`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.5.0

`innodb_cleaner_lsn_age_factor`

- Description: XtraDB has enhanced page cleaner heuristics, and with these in place, the default InnoDB adaptive flushing may be too aggressive. As a result, a new LSN age factor formula has been introduced, controlled by this variable. The default setting, `high_checkpoint`, uses the new formula, while the alternative, `legacy`, uses the original algorithm. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `--innodb-cleaner-lsn-age-factor=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Default Value:
    - `deprecated`
- Valid Values:
    - `deprecated`, `high_checkpoint`, `legacy`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_cmp_per_index_enabled`

- Description: If set to `ON` (`OFF` is default), per-index compression statistics are stored in the INFORMATION_SCHEMA.INNODB_CMP_PER_INDEX table. These are expensive to record, so this setting should only be changed with care, such as for performance tuning on development or replica servers.
- Command line: `--innodb-cmp-per-index-enabled={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.0

`innodb_commit_concurrency`

- Description: Limit to the number of transaction threads that can commit simultaneously. 0, the default, imposes no limit. While you can change from one positive limit to another at runtime, you cannot set this variable to 0, or change it from 0, while the server is running. Deprecated and ignored from MariaDB 10.5.5.
- Command line: `--innodb-commit-concurrency=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `1000`
- Deprecated: MariaDB 10.5.5
- Removed: MariaDB 10.6.0

`innodb_compression_algorithm`

- Description: Compression algorithm used for InnoDB page compression. The supported values are:
  - `none`: Pages are not compressed.
  - `zlib`: Pages are compressed using the bundled zlib compression algorithm.
  - `lz4`: Pages are compressed using the lz4 compression algorithm.
  - `lzo`: Pages are compressed using the lzo compression algorithm.
  - `lzma`: Pages are compressed using the lzma compression algorithm.
  - `bzip2`: Pages are compressed using the bzip2 compression algorithm.
  - `snappy`: Pages are compressed using the snappy algorithm.
  - On many distributions, MariaDB may not support all page compression algorithms by default. From MariaDB 10.7, libraries can be installed as a plugin. See Compression Plugins.
  - See InnoDB Page Compression: Configuring the InnoDB Page Compression Algorithm for more information.
- Command line: `--innodb-compression-algorithm=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Default Value: `zlib`
- Valid Values: `none`, `zlib`, `lz4`, `lzo`, `lzma`, `bzip2` or `snappy`

`innodb_compression_default`

- Description: Whether or not InnoDB page compression is enabled by default for new tables.
  - The default value is `OFF`, which means new tables are not compressed.
  - See InnoDB Page Compression: Enabling InnoDB Page Compression by Default for more information.
- Command line: `--innodb-compression-default={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_compression_failure_threshold_pct`

- Description: Specifies the percentage cutoff for expensive compression failures during updates to a table that uses InnoDB page compression, after which free space is added to each new compressed page, dynamically

adjusted up to the level set by innodb_compression_pad_pct_max. Zero disables checking of compression efficiency and adjusting padding.
    - See InnoDB Page Compression: Configuring the Failure Threshold and Padding for more information.
- Command line: `--innodb-compression-failure-threshold-pct=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `5`
- Range: `0` to `100`
- Introduced: MariaDB 10.0

`innodb_compression_level`

- Description: Specifies the default level of compression for tables that use InnoDB page compression.
    - Only a subset of InnoDB page compression algorithms support compression levels. If an InnoDB page compression algorithm does not support compression levels, then the compression level value is ignored.
    - The compression level can be set to any value between `1` and `9`. The default compression level is `6`. The range goes from the fastest to the most compact, which means that `1` is the fastest and `9` is the most compact.
    - See InnoDB Page Compression: Configuring the Default Compression Level for more information.
- Command line: `--innodb-compression-level=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `6`
- Range: `1` to `9`
- Introduced: MariaDB 10.0

`innodb_compression_pad_pct_max`

- Description: The maximum percentage of reserved free space within each compressed page for tables that use InnoDB page compression. Reserved free space is used when the page's data is reorganized and might be recompressed. Only used when innodb_compression_failure_threshold_pct is not zero, and the rate of compression failures exceeds its setting.
    - See InnoDB Page Compression: Configuring the Failure Threshold and Padding for more information.
- Command line: `--innodb-compression-pad-pct-max=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `50`
- Range: `0` to `75`
- Introduced: MariaDB 10.0

`innodb_concurrency_tickets`

- Description: Number of times a newly-entered thread can enter and leave InnoDB until it is again subject to the limitations of innodb_thread_concurrency and may possibly be queued. Deprecated and ignored from MariaDB 10.5.5.

- Command line: `--innodb-concurrency-tickets=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `0` (>= MariaDB 10.5.5)
  - `5000` (<= MariaDB 10.5.4)
- Range: `1` to `18446744073709551615`
- Deprecated: MariaDB 10.5.5
- Removed: MariaDB 10.6.0

`innodb_corrupt_table_action`

- Description: What action to perform when a corrupt table is found. XtraDB only.
  - When set to `assert`, the default, XtraDB will intentionally crash the server when it detects corrupted data in a single-table tablespace, with an assertion failure.
  - When set to `warn`, it will pass corruption as corrupt table instead of crashing, and disable all further I/O (except for deletion) on the table file.
  - If set to `salvage`, read access is permitted, but corrupted pages are ignored. innodb_file_per_table must be enabled for this option. Previously named `innodb_pass_corrupt_table`.
  - Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-corrupt-table-action=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value:
  - `assert` (<= MariaDB 10.1)
  - `deprecated` (<= MariaDB 10.2.6)
- Valid Values:
  - `deprecated`, `assert`, `warn`, `salvage`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_data_file_buffering`

- Description: Whether to enable the file system cache for data files. Set to `OFF` by default, are set to `ON` if innodb_flush_method is set to `fsync`, `littlesync`, `nosync`, or (Windows specific) `normal`.
- Command line: `--innodb-data-file-buffering={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 11.0.0

`innodb_data_file_path`

- Description: Individual InnoDB data files, paths and sizes. The value of innodb_data_home_dir is joined to each path specified by innodb_data_file_path to get the full directory path. If innodb_data_home_dir is an empty string, absolute paths can be specified here. A file size is specified (with K for kilobytes, M for megabytes and G for gigabytes). Also whether or not to `autoextend` the data file, and whether or not to autoshrink on startup may also be specified.
- Command line: `--innodb-data-file-path=name`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `ibdata1:12M:autoextend` (from MariaDB 10.0), `ibdata1:10M:autoextend` (before MariaDB 10.0)

`innodb_data_file_write_through`

- Description: Whether writes to InnoDB data files (including the temporary tablespace) are write through. Set to `OFF` by default, are set to `ON` if innodb_flush_method is set to `O_DSYNC`. On systems that support FUA it may make sense to enable write-through, to avoid extra system calls. See InnoDB Flush Method for a discussion of FUA and write-through behavior.
- Command line: `--innodb-data-file-write-through={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 11.0.0

`innodb_data_home_dir`

- Description: Directory path for all InnoDB data files in the shared tablespace (assuming innodb_file_per_table is not enabled). File-specific information can be added in innodb_data_file_path, as well as absolute paths if innodb_data_home_dir is set to an empty string.
- Command line: `--innodb-data-home-dir=path`
- Scope: Global
- Dynamic: No
- Data Type: `directory name`
- Default Value: `The MariaDB data directory`

`innodb_deadlock_detect`

- Description: By default, the InnoDB deadlock detector is enabled. If set to off, deadlock detection is disabled and MariaDB will rely on innodb_lock_wait_timeout instead. This may be more efficient in systems with high concurrency as deadlock detection can cause a bottleneck when a number of threads have to wait for the same lock.
- Command line: `--innodb-deadlock-detect`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `1`

`innodb_deadlock_report`

- Description: How to report deadlocks (if innodb_deadlock_detect=ON).
  - `off`: Do not report any details of deadlocks.
  - `basic`: Report transactions and waiting locks.
  - `full`: Default. Report transactions, waiting locks and blocking locks.
- Command line: `--innodb-deadlock-report=val`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Default Value: `full`
- Valid Values: `off`, `basic`, `full`
- Introduced: MariaDB 10.6.0

`innodb_default_page_encryption_key`

- Description: Encryption key used for page encryption.
  - See Data-at-Rest Encryption and InnoDB Encryption Keys for more information.
- Command line: `--innodb-default-page-encryption-key=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`
- Range: `1` to `255`
- Introduced: MariaDB 10.1.3
- Removed: MariaDB 10.1.4

`innodb_default_encryption_key_id`

- Description: ID of encryption key used by default to encrypt InnoDB tablespaces.
  - See Data-at-Rest Encryption and InnoDB Encryption Keys for more information.
- Command line: `--innodb-default-encryption-key-id=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`
- Range: `1` to `4294967295`

`innodb_default_row_format`

- Description: Specifies the default row format to be used for InnoDB tables. The compressed row format cannot be set as the default.
  - See InnoDB Row Formats Overview: Default Row Format for more information.
- Command line: `--innodb-default-row-format=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Default Value: `dynamic`

- Valid Values: `redundant`, `compact` or `dynamic`

`innodb_defragment`

- Description: When set to `1` (the default is `0`), InnoDB defragmentation is enabled. When set to FALSE, all existing defragmentation are paused and new defragmentation commands will fail. Paused defragmentation commands will resume when this variable is set to true again. See Defragmenting InnoDB Tablespaces.
- Command line: `--innodb-defragment={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 11.0.1
- Removed: MariaDB 11.1.0

`innodb_defragment_fill_factor`

- Description:. Indicates how full defragmentation should fill a page. Together with innodb_defragment_fill_factor_n_recs ensures defragmentation won't pack the page too full and cause page split on the next insert on every page. The variable indicating more defragmentation gain is the one effective. See Defragmenting InnoDB Tablespaces.
- Command line: `--innodb-defragment-fill-factor=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `double`
- Default Value: `0.9`
- Range: `0.7` to `1`
- Deprecated: MariaDB 11.0.1
- Removed: MariaDB 11.1.0

`innodb_defragment_fill_factor_n_recs`

- Description: Number of records of space that defragmentation should leave on the page. This variable, together with innodb_defragment_fill_factor, is introduced so defragmentation won't pack the page too full and cause page split on the next insert on every page. The variable indicating more defragmentation gain is the one effective. See Defragmenting InnoDB Tablespaces.
- Command line: `--innodb-defragment-fill-factor-n-recs=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `20`
- Range: `1` to `100`
- Deprecated: MariaDB 11.0.1
- Removed: MariaDB 11.1.0

`innodb_defragment_frequency`

- Description: Maximum times per second for defragmenting a single index. This controls the number of times the defragmentation thread can request X_LOCK on an index. The defragmentation thread will check whether 1/defragment_frequency (s) has passed since it last worked on this index, and put the index back in the queue if

not enough time has passed. The actual frequency can only be lower than this given number. See Defragmenting InnoDB Tablespaces.

- Command line: `--innodb-defragment-frequency=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `integer`
- Default Value: `40`
- Range: `1` to `1000`
- Deprecated: MariaDB 11.0.1
- Removed: MariaDB 11.1.0

`innodb_defragment_n_pages`

- Description: Number of pages considered at once when merging multiple pages to defragment. See Defragmenting InnoDB Tablespaces.
- Command line: `--innodb-defragment-n-pages=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `7`
- Range: `2` to `32`
- Deprecated: MariaDB 11.0.1
- Removed: MariaDB 11.1.0

`innodb_defragment_stats_accuracy`

- Description: Number of defragment stats changes there are before the stats are written to persistent storage. Defaults to zero, meaning disable defragment stats tracking. See Defragmenting InnoDB Tablespaces.
- Command line: `--innodb-defragment-stats-accuracy=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `4294967295`
- Deprecated: MariaDB 11.0.1
- Removed: MariaDB 11.1.0

`innodb_dict_size_limit`

- Description: Size in bytes of a soft limit the memory used by tables in the data dictionary. Once this limit is reached, XtraDB will attempt to remove unused entries. If set to `0`, the default and standard InnoDB behavior, there is no limit to memory usage. Removed in MariaDB 10.0/XtraDB 5.6 and replaced by MySQL 5.6's new table_definition_cache implementation.
- Command line: `innodb-dict-size-limit=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`

- Default Value - 32 bit: `2147483648`
- Default Value - 64 bit: `9223372036854775807`
- Removed: MariaDB 10.0 - replaced by MySQL 5.6's table_definition_cache implementation.

`innodb_disable_sort_file_cache`

- Description: If set to `1` (`0` is default), the operating system file system cache for merge-sort temporary files is disabled.
- Command line: `--innodb-disable-sort-file-cache={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_disallow_writes`

- Description: Tell InnoDB to stop any writes to disk.
- Command line: None
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.3.35, MariaDB 10.4.25, MariaDB 10.5.16, MariaDB 10.6.8, MariaDB 10.7.4

`innodb_doublewrite`

> **CURRENT**
>
> - Description: If set to `ON`, the default, to improve fault tolerance InnoDB first stores data to a doublewrite buffer before writing it to data file. Disabling will provide a marginal performance improvement, and assumes that writes of innodb_page_size are atomic. `fast` is available from MariaDB 11.0.6, and is like `ON`, but writes are not synchronized to data files. The deprecated start-up parameter innodb_flush_method=NO_FSYNC will cause `innodb_doublewrite=ON` to be changed to `innodb_doublewrite=fast`, which will prevent InnoDB from making any durable writes to data files. This is normally done right before the log checkpoint LSN is updated. Depending on the file systems being used and their configuration, this may or may not be safe.
>
> The value `innodb_doublewrite=fast` differs from the previous combination of `innodb_doublewrite=ON` and `innodb_flush_method=O_DIRECT_NO_FSYNC` by always invoking `os_file_flush()` on the doublewrite buffer itself in `buf_dblwr_t::flush_buffered_writes_completed()`. This is safer when there are multiple doublewrite batches between checkpoints.
>
> Typically, once per second, `buf_flush_page_cleaner()` writes out up to `innodb_io_capacity` pages and advance the log checkpoint. Also typically, `innodb_io_capacity` > `128`, which is the size of the doublewrite buffer in pages. If `os_file_flush_func()` is not invoked between doublewrite batches, writes may be reordered in an unsafe way.
>
> The setting `innodb_doublewrite=fast` can be safe when the doublewrite buffer (the first file of the system tablespace) and the data files reside on the same file system.
> - Command line: `--innodb-doublewrite{=val}`, `--skip-innodb-doublewrite`
> - Scope: Global
> - Dynamic: Yes

- Data Type: `enum`
- Default Value: `ON`
- Valid Values: `OFF`, `ON`, `fast`

< MARIADB 11.0.6

- Description: If set to `1`, the default, to improve fault tolerance InnoDB first stores data to a doublewrite buffer before writing it to data file. Disabling will provide a marginal performance improvement.
- Command line: `--innodb-doublewrite`, `--skip-innodb-doublewrite`
- Scope: Global
- Dynamic:No
- Data Type: `boolean`
- Default Value: `ON`

`innodb_doublewrite_file`

- Description: The absolute or relative path and filename to a dedicated tablespace for the doublewrite buffer. In heavy workloads, the doublewrite buffer can impact heavily on the server, and moving it to a different drive will reduce contention on random reads. Since the doublewrite buffer is mostly sequential writes, a traditional HDD is a better choice than SSD. This Percona XtraDB variable has not been ported to XtraDB 5.6.
- Command line: `innodb-doublewrite-file=filename`
- Scope: Global
- Dynamic: No
- Data Type: `filename`
- Default Value: `NULL`
- Removed: MariaDB 10.0

`innodb_empty_free_list_algorithm`

- Description: XtraDB 5.6.13-61 introduced an algorithm to assist with reducing mutex contention when the buffer pool free list is empty, controlled by this variable. If set to `backoff`, the new algorithm is used. If set to `legacy`, the original InnoDB algorithm is used. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades. See #1651657 for the reasons this was changed back to `legacy` in XtraDB 5.6.36-82.0.
- Command line: `innodb-empty-free-list-algorithm=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Default Value: `deprecated`
- Valid Values: `deprecated`, `backoff`, `legacy`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_enable_unsafe_group_commit`

- Description: Unneeded after XtraDB 1.0.5. If set to `0`, the default, InnoDB keep transactions between the transaction log and binary log is in the same order. Safer, but slower. If set to `1`, transactions can be group-committed, but there is no guarantee of the order being kept, and a small risk of the two logs getting out of sync. In write-intensive environments, can lead to a significant improvement in performance.

- Command line: `--innodb-enable-unsafe-group-commit`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `1`
- Removed: Not needed after XtraDB 1.0.5

`innodb_encrypt_log`

- Description: Enables encryption of the InnoDB redo log. This also enables encryption of some temporary files created internally by InnoDB, such as those used for merge sorts and row logs.
  - See Data-at-Rest Encryption and Enabling InnoDB Encryption: Enabling Encryption for the Redo Log for more information.
- Command line: `--innodb-encrypt-log`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_encrypt_tables`

- Description: Enables automatic encryption of all InnoDB tablespaces.
  - `OFF` - Disables table encryption for all new and existing tables that have the ENCRYPTED table option set to `DEFAULT`.
  - `ON` - Enables table encryption for all new and existing tables that have the ENCRYPTED table option set to `DEFAULT`, but allows unencrypted tables to be created.
  - `FORCE` - Enables table encryption for all new and existing tables that have the ENCRYPTED table option set to `DEFAULT`, and doesn't allow unencrypted tables to be created (`CREATE TABLE ... ENCRYPTED=NO` fails).
  - See Data-at-Rest Encryption and Enabling InnoDB Encryption: Enabling Encryption for Automatically Encrypted Tablespaces for more information.
- Command line: `--innodb-encrypt-tables={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Valid Values: `ON`, `OFF`, `FORCE`

`innodb_encrypt_temporary_tables`

- Description: Enables automatic encryption of the InnoDB temporary tablespace.
  - See Data-at-Rest Encryption and InnoDB Enabling Encryption: Enabling Encryption for Temporary Tablespaces for more information.
- Command line: `--innodb-encrypt-temporary-tables={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`

- Valid Values: `ON`, `OFF`
- Introduced: MariaDB 10.2.26, MariaDB 10.3.17, MariaDB 10.4.7

`innodb_encryption_rotate_key_age`

- Description: Re-encrypt in background any page having a key older than this number of key versions. When setting up encryption, this variable must be set to a non-zero value. Otherwise, when you enable encryption through innodb_encrypt_tables MariaDB won't be able to automatically encrypt any unencrypted tables.
  - See Data-at-Rest Encryption and InnoDB Encryption Keys: Key Rotation for more information.
- Command line: `--innodb-encryption-rotate-key-age=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`
- Range: `0` to `4294967295`

`innodb_encryption_rotation_iops`

- Description: Use this many iops for background key rotation operations performed by the background encryption threads.
  - See Data-at-Rest Encryption and InnoDB Encryption Keys: Key Rotation for more information.
- Command line: `--innodb-encryption-rotation_iops=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `100`
- Range: `0` to `4294967295`

`innodb_encryption_threads`

- Description: Number of background encryption threads performing background key rotation and scrubbing. When setting up encryption, this variable must be set to a non-zero value. Otherwise, when you enable encryption through innodb_encrypt_tables MariaDB won't be able to automatically encrypt any unencrypted tables. Recommended never be set higher than 255.
  - See Data-at-Rest Encryption and InnoDB Background Encryption Threads for more information.
- Command line: `--innodb-encryption-threads=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range:
  - `0` to `4294967295` (<= MariaDB 10.1.45, MariaDB 10.2.32, MariaDB 10.3.23, MariaDB 10.4.13, MariaDB 10.5.3)
  - `0` to `255` (>= MariaDB 10.1.46, MariaDB 10.2.33, MariaDB 10.3.24, MariaDB 10.4.14, MariaDB 10.5.4)

`innodb_extra_rsegments`

- Description: Removed in XtraDB 5.5 and replaced by innodb_rollback_segments. Usually there is one rollback segment protected by single mutex, a source of contention in high write environments. This option specifies a

number of extra user rollback segments. Changing the default will make the data readable by XtraDB only, and is incompatible with InnoDB. After modifying, the server must be slow-shutdown. If there is existing data, it must be dumped before changing, and re-imported after the change has taken effect.

- Command line: `--innodb-extra-rsegments=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `126`
- Removed: XtraDB 5.5 - replaced by innodb_rollback_segments

`innodb_extra_undoslots`

- Description: Usually, InnoDB has 1024 undo slots in its rollback segment, so 1024 transactions can run in parallel. New transactions will fail if all slots are used. Setting this variable to `1` expands the available undo slots to 4072. Not recommended unless you get the `Warning: cannot find a free slot for an undo log` error in the error log, as it makes data files unusable for ibbackup, or MariaDB servers not run with this option. See also undo log.
- Command line: `--innodb-extra-undoslots={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: XtraDB 5.5

`innodb_fake_changes`

- Description: From MariaDB 5.5 until MariaDB 10.1, XtraDB-only option that enables the fake changes feature. In replication, setting up or restarting a replica can cause a replication reads to perform more slowly, as MariaDB is single-threaded and needs to read the data before it can execute the queries. This can be speeded up by prefetching threads to warm the server, replaying the statements and then rolling back at commit. This however has an overhead from locking rows only then to undo changes at rollback. Fake changes attempts to reduce this overhead by reading the rows for `INSERT`, `UPDATE`, and `DELETE` statements but not updating them. The rollback is then very fast with little or nothing to do. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades. Not present in MariaDB 10.3 and beyond.
- Command line: `--innodb-fake-changes={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_fast_checksum`

- Description: Implements a more CPU efficient XtraDB checksum algorithm, useful for write-heavy loads with high I/O. If set to `1` on a server with tables that have been created with it set to `0`, reads are slower, so tables should be recreated (dumped and reloaded). XtraDB fails to start if set to `0` and there are tables created while set to `1`. Replaced with innodb_checksum_algorithm in MariaDB 10.0/XtraDB 5.6.

- Command line: `--innodb-fast-checksum={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.0/XtraDB 5.6 - replaced with innodb_checksum_algorithm

`innodb_fast_shutdown`

- Description: The shutdown mode:
  - `0` - InnoDB performs a slow shutdown, including full purge (before MariaDB 10.3.6, not always, due to MDEV-13603) and change buffer merge. Can be very slow, even taking hours in extreme cases.
  - `1` - the default, InnoDB performs a fast shutdown, not performing a full purge or an insert buffer merge.
  - `2`, the InnoDB redo log is flushed and a cold shutdown takes place, similar to a crash. The resulting startup then performs crash recovery. Extremely fast, in cases of emergency, but risks corruption. Not suitable for upgrades between major versions!
  - `3` (from MariaDB 10.3.6) - active transactions will not be rolled back, but all changed pages are written to data files. The active transactions are rolled back by a background thread on a subsequent startup. The fastest option that will not involve InnoDB redo log apply on subsequent startup. See MDEV-15832.
- Command line: `--innodb-fast-shutdown[=#]`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`
- Range: `0` to `3` (>= MariaDB 10.3.6), `0` to `2` (<= MariaDB 10.3.5)

`innodb_fatal_semaphore_wait_threshold`

- Description: In MariaDB, the fatal semaphore timeout is configurable. This variable sets the maximum number of seconds for semaphores to time out in InnoDB.
- Command line: `--innodb-fatal-semaphore-wait-threshold=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `600`
- Range: `1` to `4294967295`

`innodb_file_format`

- Description: File format for new InnoDB tables. Can either be `Antelope`, the default and the original format, or `Barracuda`, which supports compression. Note that this value is also used when a table is re-created with an ALTER TABLE which requires a table copy. See XtraDB/InnoDB File Format for more on the file formats. Removed in 10.3.1 and restored as a deprecated and unused variable in 10.4.3 for compatibility purposes.
- Command line: `--innodb-file-format=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`
- Default Value:
  - `Barracuda`

- Valid Values: `Antelope`, `Barracuda`
- Deprecated: MariaDB 10.2
- Removed: MariaDB 10.3.1
- Re-introduced: MariaDB 10.4.3 (for compatibility purposes)
- Removed: MariaDB 10.6.0

`innodb_file_format_check`

- Description: If set to `1`, the default, InnoDB checks the shared tablespace file format tag. If this is higher than the current version supported by XtraDB/InnoDB (for example Barracuda when only Antelope is supported), XtraDB/InnoDB will not start. If it the value is not higher, XtraDB/InnoDB starts correctly and the innodb_file_format_max value is set to this value. If `innodb_file_format_check` is set to `0`, no checking is performed. See XtraDB/InnoDB File Format for more on the file formats.
- Command line: `--innodb-file-format-check={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.2
- Removed: MariaDB 10.3.1

`innodb_file_format_max`

- Description: The highest XtraDB/InnoDB file format. This is set to the value of the file format tag in the shared tablespace on startup (see innodb_file_format_check). If the server later creates a higher table format, `innodb_file_format_max` is set to that value. See XtraDB/InnoDB File Format for more on the file formats.
- Command line: `--innodb-file-format-max=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`
- Default Value: `Antelope`
- Valid Values: `Antelope`, `Barracuda`
- Deprecated: MariaDB 10.2
- Removed: MariaDB 10.3.1

`innodb_file_per_table`

- Description: If set to `ON`, then new InnoDB tables are created with their own InnoDB file-per-table tablespaces. If set to `OFF`, then new tables are created in the InnoDB system tablespace instead. Page compression is only available with file-per-table tablespaces. Note that this value is also used when a table is re-created with an ALTER TABLE which requires a table copy. Deprecated in MariaDB 11.0 as there's no benefit to setting to `OFF`, the original InnoDB default.
- Command line: `--innodb-file-per-table`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 11.0.1

`innodb_fill_factor`

- Description: Percentage of B-tree page filled during bulk insert (sorted index build). Used as a hint rather than an absolute value. Setting to `70`, for example, reserves 30% of the space on each B-tree page for the index to grow in future.
- Command line: `--innodb-fill-factor=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `100`
- Range: `10` to `100`

`innodb_flush_log_at_timeout`

- Description: Interval in seconds to write and flush the InnoDB redo log. Before MariaDB 10, this was fixed at one second, which is still the default, but this can now be changed. It's usually increased to reduce flushing and avoid impacting performance of binary log group commit.
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`
- Range: `0` to `2700`

`innodb_flush_log_at_trx_commit`

- Description: Set to `1`, along with sync_binlog=1 for the greatest level of fault tolerance. The value of innodb_use_global_flush_log_at_trx_commit determines whether this variable can be reset with a `SET` statement or not.
  - `1` The default, the log buffer is written to the InnoDB redo log file and a flush to disk performed after each transaction. This is required for full ACID[11] compliance.
  - `0` Nothing is done on commit; rather the log buffer is written and flushed to the InnoDB redo log once a second. This gives better performance, but a server crash can erase the last second of transactions.
  - `2` The log buffer is written to the InnoDB redo log after each commit, but flushing takes place every innodb_flush_log_at_timeout seconds (by default once a second). Performance is slightly better, but a OS or power outage can cause the last second's transactions to be lost.
  - `3` The log buffer is written to the InnoDB redo log file and flushed to disk at both the prepare and the commit phase of each transaction. This is slower than `1`, and the extra flush at prepare is usually redundant. Like `1`, it guarantees that after a crash, committed transactions are not lost and remain consistent with the binary log and other transactional engines. See Binlog group commit and innodb_flush_log_at_trx_commit.
- Command line: `--innodb-flush-log-at-trx-commit[=#]`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `1`
- Valid Values: `0`, `1`, `2` or `3`

Note: When the InnoDB-based Binary Log is enabled (`--binary-storage-engine=innodb`), this option manages the durability of commits for both binlog files and InnoDB table data. Also, in this configuration, there is no separate binlog `fsync` step and no two-phase commit between InnoDB and the binary log.

`innodb_flush_method`

CURRENT

- Description: InnoDB flushing method. **Deprecated from MariaDB 11.0.** The variable can still be set, but the preferred way to control flushing behavior is to use `SET GLOBAL` on the four replacement Boolean dynamic parameters, which can be changed while the server is running:
  - innodb_log_file_buffering (enable file system cache on the InnoDB write-ahead log; added in 10.8.4, 10.9.2)
  - innodb_data_file_buffering (enable file system cache on data files)
  - innodb_log_file_write_through (enable write-through on the log)
  - innodb_data_file_write_through (enable write-through on persistent data files)
- For the full discussion of buffering, write-through, FUA, and the flag names used as values, see InnoDB Flush Method and Storage I/O: Buffering and Persistence.
- When `innodb_flush_method` is set, the value is translated into the four Boolean parameters as follows:
  - `O_DSYNC`: innodb_log_file_write_through=ON, innodb_data_file_write_through=ON, innodb_data_file_buffering=OFF, and (if supported) innodb_log_file_buffering=OFF.
  - `fsync`, `littlesync`, `nosync`, or (on Windows) `normal`: innodb_log_file_write_through=OFF, innodb_data_file_write_through=OFF, and innodb_data_file_buffering=ON.
- Command line: `--innodb-flush-method=name`
- Scope: Global
- Dynamic: No
- Data Type: `enumeration`
- Default Value:
  - `O_DIRECT` (Unix, >= MariaDB 10.6.0)
  - `fsync` (only in MariaDB < 10.5)
- Valid Values:
  - Unix: `fsync`, `O_DSYNC`, `littlesync`, `nosync`, `O_DIRECT`, `O_DIRECT_NO_FSYNC`
  - Windows: `unbuffered`, `async_unbuffered`, `normal`
- Deprecated: MariaDB 11.0

< MARIADB 11.0

- Description: InnoDB flushing method. Windows always uses `async_unbuffered`, meaning that this variable has no effect. Adjusting this variable can give performance improvements, but behavior differs widely on different filesystems. Changing from the default value may cause problems in some situations, so test and benchmark carefully before adjusting. In MariaDB, Windows recognizes and correctly handles the Unix methods, but if no methods are specified, it uses its own default – unbuffered write (analog of `O_DIRECT`) plus syncs (for instance, `FileFlushBuffers()`) for all files.
- A detailed description of the variable and its effects can be found on this page.
  - `O_DSYNC` is used to open and flush logs, and `fsync()` to flush the data files.
  - `O_DIRECT` is used to open data files, and `fsync()` to flush data and logs. This is the default on Unix from MariaDB 10.6.
  - `O_DIRECT_NO_FSYNC` uses `O_DIRECT` during flushing I/O, but skips `fsync()` afterwards. Not suitable for XFS filesystems. Generally not recommended over `O_DIRECT`, as it does not get the benefit of innodb_use_native_aio=ON.
  - `unbuffered` - Windows-only default
  - `async_unbuffered` - Windows-only, alias for `unbuffered`

    - `normal` - Windows-only, alias for `fsync`
    - `littlesync` - for internal testing only
    - `nosync` - for internal testing only
- Command line: `--innodb-flush-method=name`
- Scope: Global
- Dynamic: No
- Data Type: `enumeration`
- Default Value:
    - `O_DIRECT` (Unix, >= MariaDB 10.6.0)
    - `fsync` (only in MariaDB < 10.5)
- Valid Values:
    - Unix: `fsync`, `O_DSYNC`, `littlesync`, `nosync`, `O_DIRECT`, `O_DIRECT_NO_FSYNC`
    - Windows: `unbuffered`, `async_unbuffered`, `normal`

`innodb_flush_neighbor_pages`

- Description: Determines whether, when dirty pages are flushed to the data file, neighboring pages in the data file are flushed at the same time. If set to `none`, the feature is disabled. If set to `area`, the default, the standard InnoDB behavior is used. For each page to be flushed, dirty neighboring pages are flushed too. If there's little head seek delay, such as SSD or large enough write buffer, one of the other two options may be more efficient. If set to `cont`, for each page to be flushed, neighboring contiguous blocks are flushed at the same time. Being contiguous, a sequential I/O is used, unlike the random I/O used in `area`. Replaced by innodb_flush_neighbors in MariaDB 10.0/XtraDB 5.6.
- Command line: `innodb-flush-neighbor-pages=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `area`
- Valid Values: `none` or `0`, `area` or `1`, `cont` or `2`
- Removed: MariaDB 10.0/XtraDB 5.6 - replaced by innodb_flush_neighbors

`innodb_flush_neighbors`

- Description: Determines whether flushing a page from the buffer pool will flush other dirty pages in the same group of pages (extent). In high write environments, if flushing is not aggressive enough, it can fall behind resulting in higher memory usage, or if flushing is too aggressive, cause excess I/O activity. SSD devices, with low seek times, would be less likely to require dirty neighbor flushing to be set. Since MariaDB 10.4.4 an attempt is made under Windows and Linux to determine SSD status which was exposed in information_schema.innodb_tablespaces_scrubbing_table. This variable is ignored for table spaces that are detected as stored on SSD (and the `0` behavior applies).
    - `1`: The default, flushes contiguous dirty pages in the same extent from the buffer pool.
    - `0`: No other dirty pages are flushed.
    - `2`: Flushes dirty pages in the same extent from the buffer pool.
- Command line: `--innodb-flush-neighbors=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`

- Default Value: `1`
- Valid Values: `0`, `1`, `2`

`innodb_flush_sync`

- Description: If set to `ON`, the default, the innodb_io_capacity setting is ignored for I/O bursts occurring at checkpoints.
- Command line: `--innodb-flush-sync={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_flushing_avg_loops`

- Description: Determines how quickly adaptive flushing will respond to changing workloads. The value is the number of iterations that a previously calculated flushing state snapshot is kept. Increasing the value smooths and slows the rate that the flushing operations change, while decreasing it causes flushing activity to spike quickly in response to workload changes.
- Command line: `--innodb-flushing-avg-loops=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `30`
- Range: `1` to `1000`

`innodb_force_load_corrupted`

- Description: Set to `0` by default, if set to `1`, InnoDB are permitted to load tables marked as corrupt. Only use this to recover data you can't recover any other way, or in troubleshooting. Always restore to `0` when the returning to regular use. Given that MDEV-11412 in MariaDB 10.5.4 aims to allow any metadata for a missing or corrupted table to be dropped, and given that MDEV-17567 and MDEV-25506 and related tasks made DDL operations crash-safe, the parameter no longer serves any purpose and was removed in MariaDB 10.6.6.
- Command line: `--innodb-force-load-corrupted`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.6.6

`innodb_force_primary_key`

- Description: If set to `1` (`0` is default) CREATE TABLEs without a primary or unique key where all keyparts are NOT NULL will not be accepted, and will return an error.
- Command line: `--innodb-force-primary-key`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_force_recovery`

- Description: InnoDB crash recovery mode. `0` is the default. The other modes are for recovery purposes only, and no data can be changed while another mode is active. Some queries relying on indexes are also blocked. See InnoDB Recovery Modes for more on mode specifics.
- Command line: `--innodb-force-recovery=#`
- Scope: Global
- Dynamic: No
- Data Type: `enumeration`
- Default Value: `0`
- Range: `0` to `6`

`innodb_foreground_preflush`

- Description: Before XtraDB 5.6.13-61.0, if the checkpoint age is in the sync preflush zone while a thread is writing to the XtraDB redo log, it will try to advance the checkpoint by issuing a flush list flush batch if this is not already being done. XtraDB has enhanced page cleaner tuning, and may already be performing furious flushing, resulting in the flush simply adding unneeded mutex pressure. Instead, the thread now waits for the flushes to finish, and then has two options, controlled by this variable. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
  - `exponential_backoff` - thread sleeps while it waits for the flush list flush to occur. The sleep time randomly progressively increases, periodically reset to avoid runaway sleeps.
  - `sync_preflush` - thread issues a flush list batch, and waits for it to complete. This is the same as is used when the page cleaner thread is not running.
- Command line: `innodb-foreground-preflush=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Default Value:
  - `deprecated`
- Valid Values:
  - `deprecated`, `exponential_backoff`, `sync_preflush`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_ft_aux_table`

- Description: Diagnostic variable intended only to be set at runtime. It specifies the qualified name (for example `test/ft_innodb`) of an InnoDB table that has a FULLTEXT index, and after being set the INFORMATION_SCHEMA tables INNODB_FT_INDEX_TABLE, INNODB_FT_INDEX_CACHE, INNODB_FT_CONFIG, INNODB_FT_DELETED, and INNODB_FT_BEING_DELETED will contain search index information for the specified table.
- Command line: `--innodb-ft-aux-table=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`

`innodb_ft_cache_size`

- Description: Cache size available for a parsed document while creating an InnoDB FULLTEXT index.

- Command line: `--innodb-ft-cache-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `8000000`

`innodb_ft_enable_diag_print`

- Description: If set to `1`, additional full-text search diagnostic output is enabled.
- Command line: `--innodb-ft-enable-diag-print={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_ft_enable_stopword`

- Description: If set to `1`, the default, a set of stopwords is associated with an InnoDB FULLTEXT index when it is created. The stopword list comes from the table set by the session variable innodb_ft_user_stopword_table, if set, otherwise the global variable innodb_ft_server_stopword_table, if that is set, or the built-in list if neither variable is set.
- Command line: `--innodb-ft-enable-stopword={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_ft_max_token_size`

- Description: Maximum length of words stored in an InnoDB FULLTEXT index. A larger limit will increase the size of the index, slowing down queries, but permit longer words to be searched for. In most normal situations, longer words are unlikely search terms.
- Command line: `--innodb-ft-max-token-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `84`
- Range: `10` to `84`

`innodb_ft_min_token_size`

- Description: Minimum length of words stored in an InnoDB FULLTEXT index. A smaller limit will increase the size of the index, slowing down queries, but permit shorter words to be searched for. For data stored in a Chinese, Japanese or Korean character set, a value of 1 should be specified to preserve functionality.
- Command line: `--innodb-ft-min-token-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `3`
- Range: `1` to `16`

`innodb_ft_num_word_optimize`

- Description: Number of words processed during each OPTIMIZE TABLE on an InnoDB FULLTEXT index. To ensure all changes are incorporated, multiple OPTIMIZE TABLE statements could be run in case of a substantial change to the index.
- Command line: `--innodb-ft-num-word-optimize=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `2000`
- Range: `1000` to `10000`

`innodb_ft_result_cache_limit`

- Description: Limit in bytes of the InnoDB FULLTEXT index query result cache per fulltext query. The latter stages of the full-text search are handled in memory, and limiting this prevents excess memory usage. If the limit is exceeded, the query returns an error.
- Command line: `--innodb-ft-result-cache-limit=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `2000000000`
- Range: `1000000` to `18446744073709551615`

`innodb_ft_server_stopword_table`

- Description: Table name containing a list of stopwords to ignore when creating an InnoDB FULLTEXT index, in the format db_name/table_name. The specified table must exist before this option is set, and must be an InnoDB table with a single column, a VARCHAR named VALUE. See also innodb_ft_enable_stopword.
- Command line: `--innodb-ft-server-stopword-table=db_name/table_name`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`
- Default Value: Empty

`innodb_ft_sort_pll_degree`

- Description: Number of parallel threads used when building an InnoDB FULLTEXT index. See also innodb_sort_buffer_size.
- Command line: `--innodb-ft-sort-pll-degree=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `2`
- Range: `1` to `32`

`innodb_ft_total_cache_size`

- Description:Total memory allocated for the cache for all InnoDB FULLTEXT index tables. A force sync is triggered if this limit is exceeded.
- Command line: `--innodb-ft-total-cache-size=#`

- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `640000000`
- Range: `32000000` to `1600000000`
- Introduced: MariaDB 10.0.9

`innodb_ft_user_stopword_table`

- Description: Table name containing a list of stopwords to ignore when creating an InnoDB FULLTEXT index, in the format db_name/table_name. The specified table must exist before this option is set, and must be an InnoDB table with a single column, a VARCHAR named VALUE. See also innodb_ft_enable_stopword.
- Command line: `--innodb-ft-user-stopword-table=db_name/table_name`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `string`
- Default Value: Empty

`innodb_ibuf_accel_rate`

- Description: Allows the insert buffer activity to be adjusted. The following formula is used: [real activity] = [default activity] * (innodb_io_capacity/100) * (innodb_ibuf_accel_rate/100). As `innodb_ibuf_accel_rate` is increased from its default value of `100`, the lowest setting, insert buffer activity is increased. See also innodb_io_capacity. This Percona XtraDB variable has not been ported to XtraDB 5.6.
- Command line: `innodb-ibuf-accel-rate=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `100`
- Range: `100` to `999999999`
- Removed: MariaDB 10.0

`innodb_ibuf_active_contract`

- Description: Specifies whether the insert buffer can be processed before it's full. If set to `0`, the standard InnoDB method is used, and the buffer is not processed until it's full. If set to `1`, the default, the insert buffer can be processed before it is full. This Percona XtraDB variable has not been ported to XtraDB 5.6.
- Command line: `innodb-ibuf-active-contract=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1`
- Range: `0` to `1`
- Removed: MariaDB 10.0

`innodb_ibuf_max_size`

- Description: Maximum size in bytes of the insert buffer. Defaults to half the size of the buffer pool so you may want to reduce if you have a very large buffer pool. If set to `0`, the insert buffer is disabled, which will cause all

secondary index updates to be performed synchronously, usually at a cost to performance. This Percona XtraDB variable has not been ported to XtraDB 5.6.

- Command line: `innodb-ibuf-max-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: 1/2 the size of the InnoDB buffer pool
- Range: `0` to 1/2 the size of the InnoDB buffer pool
- Removed: MariaDB 10.0

`innodb_idle_flush_pct`

- Description: Up to what percentage of dirty pages should be flushed when innodb finds it has spare resources to do so. Has had no effect since merging InnoDB 5.7 from mysql-5.7.9 (MariaDB 10.2.2). Deprecated in MariaDB 10.2.37, MariaDB 10.3.28, MariaDB 10.4.18 and removed in MariaDB 10.5.9.
- Command line: `--innodb-idle-flush-pct=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `100`
- Range: `0` to `100`
- Deprecated: MariaDB 10.2.37, MariaDB 10.3.28, MariaDB 10.4.18
- Removed: MariaDB 10.5.9

`innodb_immediate_scrub_data_uncompressed`

- Description: Enable scrubbing of data. See Data Scrubbing.
- Command line: `--innodb-immediate-scrub-data-uncompressed={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_import_table_from_xtrabackup`

- Description: If set to `1`, permits importing of .ibd files exported with the XtraBackup –export option. Previously named `innodb_expand_import`. Removed in MariaDB 10.0/XtraDB 5.6 and replaced with MySQL 5.6's transportable tablespaces.
- Command line: `innodb-import-table-from-xtrabackup=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `1`
- Removed: MariaDB 10.0

`innodb_instant_alter_column_allowed`

- Description:

    - If a table is altered using `ALGORITHM=INSTANT`, it can force the table to use a non-canonical format: A hidden metadata record at the start of the clustered index is used to store each column's `DEFAULT` value. This makes it possible to add new columns that have default values without rebuilding the table. Starting with MariaDB 10.4, a `BLOB` in the hidden metadata record is used to store column mappings. This makes it possible to drop or reorder columns without rebuilding the table. This also makes it possible to add columns to any position or drop columns from any position in the table without rebuilding the table. If a column is dropped without rebuilding the table, old records will contain garbage in that column's former position, and new records are written with `NULL` values, empty strings, or dummy values.
    - This is generally not a problem. However, there may be cases where you want to avoid putting a table into this format. For example, to ensure that future `UPDATE` operations after an `ADD COLUMN` are performed in-place, to reduce write amplification. (Instantly added columns are essentially always variable-length.) Also avoid bugs similar to MDEV-19916, or to be able to export tables to older versions of the server.
    - This variable has been introduced as a result, with the following values:
    - `never` (0): Do not allow instant add/drop/reorder, to maintain format compatibility with MariaDB 10.x and MySQL 5.x. If the table (or partition) is not in the canonical format, then any ALTER TABLE (even one that does not involve instant column operations) will force a table rebuild.
    - `add_last` (1, default in 10.3): Store a hidden metadata record that allows columns to be appended to the table instantly (MDEV-11369).
      In 10.4 or later, if the table (or partition) is not in this format, then any ALTER TABLE (even one that does not involve column changes) will force a table rebuild.
    - `add_drop_reorder` (2, default): From MariaDB 10.4 only. Like 'add_last', but allow the metadata record to store a column map, to support instant add/drop/reorder of columns.
- Command line: `--innodb-instant-alter-column-allowed=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enum`
- Valid Values:
    - <= MariaDB 10.3: `never`, `add_last`
    - = MariaDB 10.4: `never`, `add_last`, `add_drop_reorder`
- Default Value:
    - <= MariaDB 10.3: `add_last`
    - = MariaDB 10.4: `add_drop_reorder`
- Introduced: MariaDB 10.3.23, MariaDB 10.4.13, MariaDB 10.5.3

`innodb_instrument_semaphores`

- Description: Enable semaphore request instrumentation. This could have some effect on performance but allows better information on long semaphore wait problems.
- Command line: `--innodb-instrument-semaphores={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.2.5 (treated as if `OFF`)
- Removed: MariaDB 10.3.0

`innodb_io_capacity`

- Description: Limit on I/O activity for InnoDB background tasks, including merging data from the insert buffer and flushing pages. Should be set to around the number of I/O operations per second that system can handle, based on the type of drive/s being used. You can also set it higher when the server starts to help with the extra workload at that time, and then reduce for normal use. Ideally, opt for a lower setting, as at higher value data is removed from the buffers too quickly, reducing the effectiveness of caching. See also innodb_flush_sync.
  - See InnoDB Page Flushing: Configuring the InnoDB I/O Capacity for more information.
- Command line: `--innodb-io-capacity=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `200`
- Range: `100` to `4294967295` (2^{32}-1)

`innodb_io_capacity_max`

- Description: Upper limit to which InnoDB can extend innodb_io_capacity in case of emergency. See InnoDB Page Flushing: Configuring the InnoDB I/O Capacity for more information.
- Command line: `--innodb-io-capacity-max=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `2000` or twice innodb_io_capacity, whichever is higher.
- Range : `100` to `4294967295` (2^{32}-1)

`innodb_kill_idle_transaction`

- Description: Time in seconds before killing an idle XtraDB transaction. If set to `0` (the default), the feature is disabled. Used to prevent accidental user locks. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `9223372036854775807`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_large_prefix`

- Description: If set to `1`, tables that use specific row formats are permitted to have index key prefixes up to 3072 bytes (for 16k pages, smaller otherwise). If not set, the limit is 767 bytes.
  - This applies to the DYNAMIC and COMPRESSED row formats.
  - Removed in 10.3.1 and restored as a deprecated and unused variable in 10.4.3 for compatibility purposes.
- Command line: `--innodb-large-prefix`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`

- Default Value:
  - `ON`
- Deprecated: MariaDB 10.2
- Removed: MariaDB 10.3.1
- Re-introduced: MariaDB 10.4.3 (for compatibility purposes)
- Removed: MariaDB 10.6.0

`innodb_lazy_drop_table`

- Description: Deprecated and removed in XtraDB 5.6. DROP TABLE processing can take a long time when innodb_file_per_table is set to 1 and there's a large buffer pool. If `innodb_lazy_drop_table` is set to `1` (`0` is default), XtraDB attempts to optimize DROP TABLE processing by deferring the dropping of related pages from the buffer pool until there is time, only initially marking them.
- Command line: `innodb-lazy-drop-table={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `0`
- Deprecated: XtraDB 5.5.30-30.2
- Removed: MariaDB 10.0.0

`innodb_lock_schedule_algorithm`

- Description: Removed in MariaDB 10.6.0 due to problems with the VATS implementation (MDEV-16664). Specifies the algorithm that InnoDB uses to decide which of the waiting transactions should be granted the lock once it has been released. The possible values are: `FCFS` (First-Come-First-Served) where locks are granted in the order they appear in the lock queue and `VATS` (Variance-Aware-Transaction-Scheduling) where locks are granted based on the Eldest-Transaction-First heuristic. Note that `VATS` should not be used with Galera, and InnoDB will refuse to start if `VATS` is used with Galera. It is also not recommended to set to `VATS` even in the general case (MDEV-16664). From MariaDB 10.2.12, the value was changed to `FCFS` and a warning produced when using Galera.
- Command line: `--innodb-lock-schedule-algorithm=#`
- Scope: Global
- Dynamic: No (>= MariaDB 10.2.12, MariaDB 10.1.30), Yes (<= MariaDB 10.2.11, MariaDB 10.1.29)
- Data Type: `enum`
- Valid Values: `FCFS`, `VATS`
- Default Value: `FCFS` (MariaDB 10.3.9, MariaDB 10.2.17), `VATS` (MariaDB 10.2.3), `FCFS` (MariaDB 10.1)
- Deprecated: MariaDB 10.5.7, MariaDB 10.4.16, MariaDB 10.3.26, MariaDB 10.2.35
- Removed: MariaDB 10.6.0

`innodb_lock_wait_timeout`

- Description: Time in seconds that an InnoDB transaction waits for an InnoDB record lock (or table lock) before giving up with the error `ERROR 1205 (HY000): Lock wait timeout exceeded; try restarting transaction`. When this occurs, the statement (not transaction) is rolled back. The whole transaction can be rolled back if the innodb_rollback_on_timeout option is used. Increase this for data warehousing applications or where other long-running operations are common, or decrease for OLTP and other highly interactive applications. This setting does not apply to deadlocks, which InnoDB detects immediately, rolling back a deadlocked transaction. `0`

means no wait. See WAIT and NOWAIT. Setting to `100000000` or more (from MariaDB 10.6.3, `100000000` is the maximum) means the timeout is infinite.

- Command line: `--innodb-lock-wait-timeout=#`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `INT UNSIGNED` (>= MariaDB 10.6.3), `BIGINT UNSIGNED` (<= MariaDB 10.6.2)
- Default Value: `50`
- Range:
  - `0` to `100000000` (>= MariaDB 10.6.3)
  - `0` to `1073741824` (>= MariaDB 10.3 to <= MariaDB 10.6.2)

`innodb_locking_fake_changes`

- Description: From MariaDB 5.5 to MariaDB 10.1, XtraDB-only option that if set to `OFF`, fake transactions (see innodb_fake_changes) don't take row locks. This is an experimental feature to attempt to deal with drawbacks in fake changes blocking real locks. It is not safe for use in all environments. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `--innodb-locking-fake-changes`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_locks_unsafe_for_binlog`

- Description: Set to `0` by default, in which case XtraDB/InnoDB uses gap locking. If set to `1`, gap locking is disabled for searches and index scans. Deprecated in MariaDB 10.0, and removed in MariaDB 10.5, use READ COMMITTED transaction isolation level instead.
- Command line: `--innodb-locks-unsafe-for-binlog`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.5.0

`innodb_log_arch_dir`

- Description: The directory for XtraDB redo log archiving. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `--innodb-log-arch-dir=name`
- Scope: Global
- Dynamic: No
- Data Type: `string`
- Default Value: `./`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_log_arch_expire_sec`

- Description: Time in seconds since the last change after which the archived XtraDB redo log should be deleted. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `--innodb-log-arch-expire-sec=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_log_archive`

- Description: Controls the InnoDB log archiving format. When set to `ON`, the InnoDB write-ahead log is written to a sequence of files named `ib_` *`lsn`* `.log` instead of the circular ring buffer (`ib_logfile0`). Each file is pre-allocated to `innodb_log_file_size`; when one fills up, the server creates and pre-allocates the next file. After the first checkpoint completes in a new file, the previous file is marked read-only, signaling that it can be moved to long-term storage. This format makes a continuous log history available, which is necessary for point-in-time recovery and incremental backups.
- Details:
  - File Naming: Archive files use the naming convention `ib_` *`lsn`* `.log`, where *lsn* is a 16-character hexadecimal representation of the Log Sequence Number (LSN) at offset 12288 (0x3000) of the file.
  - Log Resizing: When archiving is enabled, changes to `innodb_log_file_size` take effect when the current log file is filled and a new file is allocated. This differs from the standard resizing logic used when `innodb_log_archive` is `OFF`.
  - Encryption: While `innodb_log_archive` is `ON`, the value of `innodb_encrypt_log` and related encryption parameters cannot be changed. To change encryption, set `innodb_log_archive=OFF` and restart the server — this permanently discards the archived log history.
  - Startup: With `innodb_log_archive=ON`, the server refuses to start if `ib_logfile0` exists in the data directory.
  - Data Dictionary: This feature tracks InnoDB changes only. It does not cover `.frm` files or other non-InnoDB metadata.
  - Backup tooling: No shipped tool yet generates or restores backups in this format. `mariadb-backup` only supports the legacy `ib_logfile0` format and fails when the server is running with `innodb_log_archive=ON`.
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 13.0

`innodb_log_block_size`

- Description: Size in bytes of the XtraDB redo log records. Generally `512`, the default, or `4096`, are the only two useful values. If the server is restarted and this value is changed, all old log files need to be removed. Should be set to `4096` for SSD cards or if innodb_flush_method is set to `ALL_O_DIRECT` on ext4 filesystems. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-log-block-size=#`

- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `512`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_log_buffer_size`

- Description: Size in bytes of the buffer for writing InnoDB redo log files to disk. Increasing this means larger transactions can run without needing to perform disk I/O before committing.
- Command line: `--innodb-log-buffer-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `16777216` (16MB)
- Range: `262144` to `2147479552` (256KB to 2GB - 4K) (>= MariaDB 10.11.8)
- Range: `262144` to `18446744073709551615` (<= MariaDB 10.11.7) - limit to the above maximum because this is an operating system limit.
- Block size: `4096`

`innodb_log_checkpoint_now`

- Description: Write back dirty pages from the buffer pool and update the log checkpoint. Prior to MariaDB 10.11.12, MariaDB 11.4.6, MariaDB 11.8.2 was only available in debug builds. Introduced in order to force checkpoints before a backup, allowing mariadb-backup to create much smaller incremental backups. However, this comes at the cost of heavy I/O usage and it is now disabled by default.
- Command line: `--innodb-log-checkpoint{=1|0}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.11.12, MariaDB 11.4.6, MariaDB 11.8.2

`innodb_log_checksum_algorithm`

- Description: Experimental feature (as of MariaDB 10.0.9), this variable specifies how to generate and verify XtraDB redo log checksums. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
  - `none` - No checksum. A constant value is instead written to logs, and no checksum validation is performed.
  - `innodb` - The default, and the original InnoDB algorithm. This is inefficient, but compatible with all MySQL, MariaDB and Percona versions that don't support other checksum algorithms.
  - `crc32` - CRC32© is used for log block checksums, which also permits recent CPUs to use hardware acceleration (on SSE4.2 x86 machines and Power8 or later) for the checksums.
  - `strict_*` - Whether or not to accept checksums from other algorithms. If strict mode is used, checksums blocks are considered corrupt if they don't match the specified algorithm. Normally they are considered corrupt only if no other algorithm matches.
- Command line: `innodb-log-checksum-algorithm=value`
- Scope: Global

- Dynamic: Yes
- Data Type: `enum`
- Default Value:
  - `deprecated` (>= MariaDB 10.2.6)
  - `innodb` (<= MariaDB 10.1)
- Valid Values:
  - `deprecated`, `innodb`, `none`, `crc32`, `strict_none`, `strict_innodb`, `strict_crc32` (>= MariaDB 10.2.6)
  - `innodb`, `none`, `crc32`, `strict_none`, `strict_innodb`, `strict_crc32` (<= MariaDB 10.1)
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_log_checksums`

- Description: If set to `1`, the CRC32C for Innodb or `innodb_log_checksum_algorithm` for XtraDB algorithm is used for InnoDB redo log pages. If disabled, the checksum field contents are ignored. From MariaDB 10.5.0, the variable is deprecated, and checksums are always calculated, as previously, the InnoDB redo log used the slow innodb algorithm, but with hardware or SIMD assisted CRC-32C computation being available, there is no reason to allow checksums to be disabled on the redo log.
- Command line: `innodb-log-checksums={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.5.0
- Removed: MariaDB 10.6.0

`innodb_log_compressed_pages`

- Description: Whether or not images of recompressed pages are stored in the InnoDB redo log. Deprecated and ignored from MariaDB 10.5.3.
- Command line: `--innodb-log-compressed-pages={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value:
  - `ON`
- Deprecated: MariaDB 10.5.3
- Removed: MariaDB 10.6.0

`innodb_log_file_buffering`

- Description: Whether the file system cache for ib_logfile0 is enabled. In MariaDB 10.8.3, MariaDB disabled the file system cache on the InnoDB write-ahead log file (ib_logfile0) by default on Linux. With innodb_flush_trx_log_at_commit=2 in particular, writing to the log via the file system cache typically improves throughput, especially on slow storage or at a small number of concurrent transactions. For other values of innodb_flush_log_at_trx_commit, direct writes were observed to be mostly but not always faster. Whether it pays off to disable the file system cache on the log may depend on the type of storage, the workload, and the operating system kernel version. If the server is started up with innodb_flush_log_at_trx_commit=2, the value are changed to `ON`. Will be set to `OFF` if innodb_flush_method is set to `O_DSYNC`. On Linux, when the physical block

size cannot be determined to be a power of 2 between 64 and 4096 bytes, the file system cache cannot be disabled, and innodb_log_file_buffering=ON cannot be changed. Linux and Windows only.

- Command line: `--innodb-log-file-buffering={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 10.8.4, MariaDB 10.9.2

> **Note:**
>
> A change requested with `SET GLOBAL innodb_log_file_buffering` takes effect only when InnoDB is holding a single log file open, which is the case most of the time. It is ignored while a `SET GLOBAL innodb_log_file_size` resize is in progress on a circular-format log (`ib_logfile0`). From MariaDB 13.0 (MDEV-39862), it is also ignored while a log file switch is in progress with `innodb_log_archive` set to `ON` , because InnoDB then has more than one log file open; when this occurs, and how long it lasts, is hard to predict, as it depends on `innodb_log_file_size` and the workload. The setting also has no effect when the log is mapped to persistent memory (PMEM).
>
> Because the request can be silently ignored, confirm that it took effect by reading the value back:
>
> ```
> SELECT @@GLOBAL.innodb_log_file_buffering;
> ```

`innodb_log_file_mmap`

- Description: Whether ib_logfile0 resides in persistent memory or should initially be memory-mapped. When using the default innodb_log_buffer_size=2m, mariadb-backup –backup would spend a lot of time re-reading and re-parsing the log. For reading the log file during mariadb-backup –backup, it is beneficial to memory-map the entire ib_logfile0 to the address space (typically 48 bits or 256 TiB) and read it from there, both during –backup and –prepare. OFF by default on most platforms, to avoid aggressive read-ahead of the entire ib_logfile0 in when only a tiny portion would be accessed. On Linux and FreeBSD the default is innodb_log_file_mmap=ON, because those platforms define a specific mmap(2) option for enabling such read-ahead and therefore it can be assumed that the default wouldbe on-demand paging. This parameter will only have impact on the initial InnoDB startup and recovery. Any writes to the log will use regular I/O, except when the ib_logfile0 is stored in a specially configured file system that is backed by persistent memory (Linux “mount -o dax”).
- Command line: `--innodb-log-file-mmap{=0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON` (Linux, FreeBSD), `OFF` (Other platforms)
- Introduced: MariaDB 10.11.10, MariaDB 11.2.6, MariaDB 11.4.4, MariaDB 11.6.2, MariaDB 11.7.1

`innodb_log_file_size`

- Description: Size in bytes of each InnoDB redo log file in the log group. The combined size can be no more than 512GB. Larger values mean less disk I/O due to less flushing checkpoint activity, but also slower recovery from a crash. In MariaDB 10.5, crash recovery has been improved and shouldn’t run out of memory, so the default has been increased. It can safely be set higher to reduce checkpoint flushing, even larger than innodb_buffer_pool_size.From MariaDB 10.9 the variable is dynamic, and the server no longer needs to be restarted for the resizing to take place. Unless the log is located in a persistent memory file system (PMEM), an attempt to SET GLOBAL innodb_log_file_size to less than innodb_log_buffer_size are refused. Log resizing can be aborted by killing the connection that is executing the SET GLOBAL statement.

- Command line: `--innodb-log-file-size=#`
- Scope: Global
- Dynamic: Yes (>= MariaDB 10.9), No (<= MariaDB 10.8)
- Data Type: `numeric`
- Default Value: `100663296` (96MB) (>= MariaDB 10.5), `50331648` (48MB) (<= MariaDB 10.4)
- Range:
  - = MariaDB 10.8.3: `4194304` to `512GB` (4MB to 512GB)
  - <= MariaDB 10.8.2: `1048576` to `512GB` (1MB to 512GB)
- Block size: `4096`

`innodb_log_file_write_through`

- Description: Whether each write to ib_logfile0 is write through (disabling any caching, as in O_SYNC or O_DSYNC). Set to `OFF` by default, are set to `ON` if innodb_flush_method is set to `O_DSYNC`. On systems that support FUA it may make sense to enable write-through, to avoid extra system calls. See InnoDB Flush Method for a discussion of FUA and write-through behavior.
- Command line: `--innodb-log-file-write-through={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 11.0.0

> **Note:**
>
> A change requested with `SET GLOBAL innodb_log_file_write_through` takes effect only when InnoDB is holding a single log file open, which is the case most of the time. It is ignored while a `SET GLOBAL innodb_log_file_size` resize is in progress on a circular-format log (`ib_logfile0`). From MariaDB 13.0 (MDEV-39862), it is also ignored while a log file switch is in progress with `innodb_log_archive` set to `ON`, because InnoDB then has more than one log file open; when this occurs, and how long it lasts, is hard to predict, as it depends on `innodb_log_file_size` and the workload. The setting also has no effect when the log is mapped to persistent memory (PMEM).
>
> Because the request can be silently ignored, confirm that it took effect by reading the value back:
>
> ```
> SELECT @@GLOBAL.innodb_log_file_write_through;
> ```

`innodb_log_files_in_group`

- Description: Number of physical files in the InnoDB redo log. Deprecated and ignored from MariaDB 10.5.2
- Command line: `--innodb-log-files-in-group=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `1` (>= MariaDB 10.5), `2` (<= MariaDB 10.4)
- Range: `1` to `100` (>= MariaDB 10.2.4)
- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_log_group_home_dir`

- Description: Path to the InnoDB redo log files. If none is specified, innodb_log_files_in_group files named ib_logfile0 and so on, with a size of innodb_log_file_size are created in the data directory.
- Command line: `--innodb-log-group-home-dir=path`
- Scope: Global
- Dynamic: No
- Data Type: `directory name`

`innodb_log_optimize_ddl`

- Description: Whether InnoDB redo log activity should be reduced when natively creating indexes or rebuilding tables. Reduced logging requires additional page flushing and interferes with mariadb-backup. Enabling this may slow down backup and cause delay due to page flushing. Deprecated and ignored from MariaDB 10.5.1. Deprecated (but not ignored) from MariaDB 10.4.16, MariaDB 10.3.26 and MariaDB 10.2.35.
- Command line: `--innodb-log-optimize-ddl={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value:
  - `OFF` (>= MariaDB 10.5.1, MariaDB 10.4.16, MariaDB 10.3.26, MariaDB 10.2.35)
  - `ON` (<= MariaDB 10.5.0, MariaDB 10.4.15, MariaDB 10.3.25, MariaDB 10.2.34)
- Introduced: MariaDB 10.2.17, MariaDB 10.3.9
- Deprecated: MariaDB 10.5.1, MariaDB 10.4.16, MariaDB 10.3.26, MariaDB 10.2.35
- Removed: MariaDB 10.6.0

`innodb_log_recovery_start`

- Description: Specifies the Log Sequence Number (LSN) at which the recovery process begins. Only meaningful when recovering a backup that contains log files in the `innodb_log_archive=ON` format.
- Usage: Set this variable to limit the scope of a recovery operation. The server expects to find an optional sequence of `FILE_MODIFY` records followed by a `FILE_CHECKPOINT` record at the specified *lsn*. This is typically used when restoring an incremental backup, by setting the variable to the end LSN of the previous restore.
- Special value: `0` (the default) means start recovery from the latest completed checkpoint. The latest checkpoint is guaranteed to live in one of the last two `ib_`*`lsn`*`.log` files in the data directory, typically the last one.
- Property: Set at startup
- Data Type: `numeric` (64-bit unsigned integer)
- Default Value: `0`
- Introduced: MariaDB 13.0

`innodb_log_recovery_target`

- Description: Specifies the target Log Sequence Number (LSN) at which the recovery process ends. Only meaningful when recovering a backup that contains log files in the `innodb_log_archive=ON` format.
- Usage: Use this variable to define a recovery point objective. The server replays archived logs up to the specified *lsn* and stops. When this variable is non-zero, all persistent InnoDB tables become read-only and no log writes are allowed.
- Special value: `0` (the default) performs an unlimited recovery — the server replays the log to its end.
- Property: Set at startup
- Data Type: `numeric` (64-bit unsigned integer)

- Default Value: `0`
- Introduced: MariaDB 13.0

> **Warning:**
>
> **No data file may carry an LSN newer than `innodb_log_recovery_target`.** Crash recovery's role is to bring every database page to the same logical point in time (the same LSN). If any data file is newer than the target, recovery completes in an inconsistent state where some pages carry an LSN past the requested target — that is, the database is corrupted. The server cannot validate every such impossible target, and the resulting corruption may not be detected until the affected pages are accessed (see MDEV-34830). Choose a target that lies at or beyond the highest page LSN you intend to retain.
>
> If you set a target that is unreachable in the other direction (for example, lower than the current checkpoint), the server terminates with an error message containing the available LSN range.

`innodb_log_spin_wait_delay`

- Description: Delay between log buffer spin lock polls (0 to use a blocking latch). Specifically, enables a spin lock that will execute that many MY_RELAX_CPU() operations (such as the x86 PAUSE instruction) between successive attempts of acquiring the spin lock. On some hardware with certain workloads (observed on write intensive workloads on NUMA[12] systems), the default setting results in a significant amount of time being spent in native_queued_spin_lock_slowpath() in the Linux kernel, plus context switching between user and kernel address space, in which case changing from the default (for example, setting to `50`), may result in a performance improvement.
- Command line: `--innodb-log-spin-wait-delay=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `6000`
- Introduced: MariaDB 10.11.8, MariaDB 11.0.6, MariaDB 11.1.5, MariaDB 11.2.4, MariaDB 11.4.2, MariaDB 11.5.1

`innodb_log_write_ahead_size`

- Description: InnoDB redo log write ahead unit size to avoid read-on-write. Should match the OS cache block IO size. Removed in MariaDB 10.8, and instead on Linux and Windows, the physical block size of the underlying storage is detected and used. Reintroduced in MariaDB 10.11.9 and later versions. On Linux and Windows, the default or the specified innodb_log_write_ahead_size are automatically adjusted to not be less than the physical block size (if it can be determined).
- Command line: `--innodb-log-write-ahead-size=#`
- Scope: Global
- Dynamic: No (>= MariaDB 10.11.9), Yes (<= MariaDB 10.7)
- Data Type: `numeric`
- Default Value: `512` (>= MariaDB 10.11.9), `8192` (<= MariaDB 10.7)
- Range:
  - `512` to `4096` (>= MariaDB 10.11.9)
  - `512` to innodb_page_size (<= MariaDB 10.7)
- Removed: MariaDB 10.8
- Re-introduced: MariaDB 10.11.9, MariaDB 11.1.6, MariaDB 11.2.5, MariaDB 11.4.3, MariaDB 11.5.2

`innodb_lru_flush_size`

- Description: Number of pages to flush on LRU eviction. Changes in MariaDB 10.6.18, MariaDB 10.11.8, MariaDB 11.0.6, MariaDB 11.1.5, MariaDB 11.2.4 and MariaDB 11.4.2 made this setting superfluous, and it is no longer used.
- Command line: `--innodb-lru-flush-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `0` (>= MariaDB 10.6.20, MariaDB 10.11.10, MariaDB 11.2.6, MariaDB 11.4.4. MariaDB 11.6.1, MariaDB 11.7.1)
  - `32` (<= MariaDB 10.6.19, MariaDB 10.11.9, MariaDB 11.2.5, MariaDB 11.4.3)
- Range: `1` to `18446744073709551615`
- Introduced: MariaDB 10.5.7
- Deprecated: MariaDB 10.6.20, MariaDB 10.11.10, MariaDB 11.2.6 and MariaDB 11.4.4. MariaDB 11.6.1, MariaDB 11.7.1

`innodb_lru_scan_depth`

- Description: Specifies how far down the buffer pool least-recently used (LRU) list the cleaning thread should look for dirty pages to flush. This process is performed once a second. In an I/O intensive-workload, can be increased if there is spare I/O capacity, or decreased if in a write-intensive workload with little spare I/O capacity.
  - See InnoDB Page Flushing for more information.
- Command line: `--innodb-lru-scan-depth=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `1536` (>= MariaDB 10.5.7)
  - `1024` (<= MariaDB 10.5.6)
- Range - 32bit: `100` to `2^32-1`
- Range - 64bit: `100` to `2^64-1`

`innodb_max_bitmap_file_size`

- Description: Limit in bytes of the changed page bitmap files. For faster incremental backup with Xtrabackup, XtraDB tracks pages with changes written to them according to the XtraDB redo log and writes the information to special changed page bitmap files. These files are rotated when the server restarts or when this limit is reached. XtraDB only. See also innodb_track_changed_pages and innodb_max_changed_pages.
  - Deprecated and ignored in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-max-bitmap-file-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `4096` (4KB)
- Range: `4096` (4KB) to `18446744073709551615` (16EB)

- Deprecated: MariaDB 10.2.6

`innodb_max_changed_pages`

- Description: Limit to the number of changed page bitmap files (stored in the Information Schema INNODB_CHANGED_PAGES table). Zero is unlimited. See innodb_max_bitmap_file_size and innodb_track_changed_pages. Previously named `innodb_changed_pages_limit`. XtraDB only.
  - Deprecated and ignored in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-max-changed-pages=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1000000`
- Range: `0` to `18446744073709551615`
- Deprecated: MariaDB 10.2.6

`innodb_max_dirty_pages_pct`

- Description: Maximum percentage of unwritten (dirty) pages in the buffer pool.
  - See InnoDB Page Flushing for more information.
- Command line: `--innodb-max-dirty-pages-pct=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `90.000000` (>= MariaDB 10.5.7)
  - `75.000000` (<= MariaDB 10.5.6)
- Range: `0` to `99.999`

`innodb_max_dirty_pages_pct_lwm`

- Description: Low water mark percentage of dirty pages that will enable preflushing to lower the dirty page ratio. The value 0 (default) means 'refer to innodb_max_dirty_pages_pct'. (Note that 0 meant 0 in 10.5.7 to 10.5.8, but was then reverted back to "same as innodb_max_dirty_pages_pct" again in 10.5.9)
  - See InnoDB Page Flushing for more information.
- Command line: `--innodb-max-dirty-pages-pct-lwm=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `0` (>= MariaDB 10.2.1)
  - `0.001` (<= MariaDB 10.2.0)
- Range: `0` to `99.999`

`innodb_max_purge_lag`

- Description: When purge operations are lagging on a busy server, setting innodb_max_purge_lag can help. By default set to `0`, no lag, the figure is used to calculate a time lag for each INSERT, UPDATE, and DELETE when

the system is lagging. InnoDB keeps a list of transactions with delete-marked index records due to UPDATE and DELETE statements. The length of this list is `purge_lag`, and the calculation, performed every ten seconds, is as follows: ((purge_lag/innodb_max_purge_lag)×10)–5 microseconds.

- Command line: `--innodb-max-purge-lag=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `4294967295`

`innodb_max_purge_lag_delay`

- Description: Maximum delay in milliseconds imposed by the innodb_max_purge_lag setting. If set to `0`, the default, there is no maximum.
- Command line: `--innodb-max-purge-lag-delay=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`

`innodb_max_purge_lag_wait`

- Description: Wait until History list length is below the specified limit.
- Command line: `--innodb-max-purge-wait=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `4294967295`
- Range: `0` to `4294967295`
- Introduced: MariaDB 10.5.7, MariaDB 10.4.16, MariaDB 10.3.26, MariaDB 10.2.35

`innodb_max_undo_log_size`

- Description: If an undo tablespace is larger than this, it is marked for truncation if innodb_undo_log_truncate is set.
- Command line: `--innodb-max-undo-log-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `10485760`
- Range: `10485760` to `18446744073709551615`

`innodb_merge_sort_block_size`

- Description: Size in bytes of the block used for merge sorting in fast index creation. Replaced in MariaDB 10.0/XtraDB 5.6 by innodb_sort_buffer_size.
- Command line: `innodb-merge-sort-block-size=#`
- Scope: Global

- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1048576` (1M)
- Range: `1048576` (1M) to `1073741824` (1G)
- Removed: MariaDB 10.0 - replaced by innodb_sort_buffer_size

`innodb_mirrored_log_groups`

- Description: Unused. Restored as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.2.2 - MariaDB 10.2.5

`innodb_mtflush_threads`

- Description: Sets the number of threads to use in Multi-Threaded Flush operations. For more information, see Fusion-io Multi-threaded Flush.
  - InnoDB's multi-thread flush feature was deprecated in MariaDB 10.2.9 and removed from MariaDB 10.3.2. In later versions of MariaDB, use innodb_page_cleaners system variable instead.
  - See InnoDB Page Flushing: Page Flushing with Multi-threaded Flush Threads for more information.
- Command line: `--innodb-mtflush-threads=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `8`
- Range: `1` to `64`
- Deprecated: MariaDB 10.2.9
- Removed: MariaDB 10.3.2

`innodb_monitor_disable`

- Description: Disables the specified counters in the INFORMATION_SCHEMA.INNODB_METRICS table.
- Command line: `--innodb-monitor-disable=string`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`

`innodb_monitor_enable`

- Description: Enables the specified counters in the INFORMATION_SCHEMA.INNODB_METRICS table.
- Command line: `--innodb-monitor-enable=string`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`

`innodb_monitor_reset`

- Description: Resets the count value of the specified counters in the INFORMATION_SCHEMA.INNODB_METRICS table to zero.
- Command line: `--innodb-monitor-reset=string`

- Scope: Global
- Dynamic: Yes
- Data Type: `string`

`innodb_monitor_reset_all`

- Description: Resets all values for the specified counters in the INFORMATION_SCHEMA.INNODB_METRICS table.
- Command line: `---innodb-monitor-reset-all=string`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`

`innodb_numa_interleave`

- Description: Whether or not to use the NUMA[13] interleave memory policy to allocate the InnoDB buffer pool.
- Command line: `innodb-numa-interleave={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.2.23, MariaDB 10.3.14, MariaDB 10.4.4

`innodb_old_blocks_pct`

- Description: Percentage of the buffer pool to use for the old block sublist.
- Command line: `--innodb-old-blocks-pct=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `37`
- Range: `5` to `95`

`innodb_old_blocks_time`

- Description: Time in milliseconds an inserted block must stay in the old sublist after its first access before it can be moved to the new sublist. '0' means "no delay". Setting a non-zero value can help prevent full table scans clogging the buffer pool. See also innodb_old_blocks_pct.
- Command line: `--innodb-old-blocks-time=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `1000`
- Range: `0` to `2^32-1`

`innodb_online_alter_log_max_size`

- Description: The maximum size for temporary log files during online DDL (data and index structure changes). The temporary log file is used for each table being altered, or index being created, to store data changes to the table while the process is underway. The table is extended by innodb_sort_buffer_size up to the limit set by this

variable. If this limit is exceeded, the online DDL operation fails and all uncommitted changes are rolled back. A lower value reduces the time a table could lock at the end of the operation to apply all the log's changes, but also increases the chance of the online DDL changes failing.

- Command line: `--innodb-online-alter-log-max-size=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `134217728`
- Range: `65536` to `2^64-1`

`innodb_open_files`

- Description: Maximum .ibd files MariaDB can have open at the same time. Only applies to systems with multiple XtraDB/InnoDB tablespaces, and is separate to the table cache and open_files_limit. The default, if innodb_file_per_table is disabled, is 300 or the value of table_open_cache, whichever is higher. It will also auto-size up to the default value if it is set to a value less than `10`.
- Command line: `--innodb-open-files=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `autosized`
- Range: `10` to `4294967295`

`innodb_optimize_fulltext_only`

- Description: When set to `1` (`0` is default), OPTIMIZE TABLE will only process InnoDB FULLTEXT index data. Only intended for use during fulltext index maintenance.
- Command line: `--innodb-optimize-fulltext-only={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_page_cleaners`

- Description: Number of page cleaner threads. The default is `4`, but the value are set to the number of innodb_buffer_pool_instances if this is lower. If set to `1`, only a single cleaner thread is used, as was the case until MariaDB 10.2.1. Cleaner threads flush dirty pages from the buffer pool, performing flush list and least-recently used (LRU) flushing. Deprecated and ignored from MariaDB 10.5.1, as the original reasons for splitting the buffer pool have mostly gone away.
  - See InnoDB Page Flushing: Page Flushing with Multiple InnoDB Page Cleaner Threads for more information.
- Command line: `--innodb-page-cleaners=#`
- Scope: Global
- Dynamic: Yes (>= MariaDB 10.3.3), No (<= MariaDB 10.3.2)
- Data Type: `numeric`
- Default Value: `4` (or set to innodb_buffer_pool_instances if lower)
- Range: `1` to `64`
- Deprecated: MariaDB 10.5.1
- Removed: MariaDB 10.6.0

`innodb_page_size`

- Description: Specifies the page size in bytes for all InnoDB tablespaces. The default, `16k`, is suitable for most uses.
  - A smaller InnoDB page size might work more effectively in a situation with many small writes (OLTP), or with SSD storage, which usually has smaller block sizes.
  - A larger InnoDB page size can provide a larger maximum row size.
  - InnoDB's page size can be as large as `64k` for tables using the following row formats: DYNAMIC, COMPACT, and REDUNDANT.
  - InnoDB's page size must still be `16k` or less for tables using the COMPRESSED row format.
  - This system variable's value cannot be changed after the `datadir` has been initialized. InnoDB's page size is set when a MariaDB instance starts, and it remains constant afterwards.
- Command line: `--innodb-page-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `enumeration`
- Default Value: `16384`
- Valid Values: `4k` or `4096`, `8k` or `8192`, `16k` or `16384`, `32k` and `64k`.

`innodb_pass_corrupt_table`

- Removed: XtraDB 5.5 - renamed innodb_corrupt_table_action.

`innodb_prefix_index_cluster_optimization`

- Description: Enable prefix optimization to sometimes avoid cluster index lookups. Deprecated and ignored from MariaDB 10.10, as the optimization is now always enabled.
- Command line: `--innodb-prefix-index-cluster-optimization={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.10.1

`innodb_print_all_deadlocks`

- Description: If set to `1` (`0` is default), all InnoDB transaction deadlock information is written to the error log.
- Command line: `--innodb-print-all-deadlocks={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_purge_batch_size`

- Description: Number of InnoDB undo log pages to purge in one batch from the history list. Together with innodb_purge_threads has a small effect on tuning.
- Command line: `--innodb-purge-batch-size=#`
- Scope: Global
- Dynamic: No

- Data Type: `numeric`
- Default Value:
  - `127` (>= MariaDB 10.6.20, MariaDB 10.11.10, MariaDB 11.2.6, MariaDB 11.4.4, MariaDB 11.6.2)
  - `1000` (>= MariaDB 10.6.16, MariaDB 10.10.7, MariaDB 10.11.6, MariaDB 11.0.4, MariaDB 11.1.3 MariaDB 11.2.2)
  - `300` (<= MariaDB 10.6.15, MariaDB 10.10.6, MariaDB 10.11.5, MariaDB 11.0.3, MariaDB 11.1.2 MariaDB 11.2.1)
- Range: `1` to `5000`

`innodb_purge_rseg_truncate_frequency`

- Description: Frequency with which undo records are purged. Set by default to every 128 times, reducing this increases the frequency at which rollback segments are freed. See also innodb_undo_log_truncate. The motivation for introducing this in MySQL seems to have been to avoid stalls due to freeing undo log pages or truncating undo log tablespaces. In MariaDB, innodb_undo_log_truncate=ON should be a much lighter operation because it will not involve any log checkpoint, hence this is deprecated and ignored from MariaDB 10.6.16, MariaDB 10.10.7, MariaDB 10.11.6, MariaDB 11.0.4, MariaDB 11.1.3 and MariaDB 11.2.2. (MDEV-32050)
- Command line: `-- innodb-purge-rseg-truncate-frequency=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `128`
- Range: `1` to `128`
- Deprecated: MariaDB 10.6.16, MariaDB 10.10.7, MariaDB 10.11.6, MariaDB 11.0.4, MariaDB 11.1.3, MariaDB 11.2.2

`innodb_purge_threads`

- Description: Number of background threads dedicated to InnoDB purge operations. The range is `1` to `32`. At least one background thread is always used. Setting to a value greater than 1 creates that many separate purge threads. This can improve efficiency in some cases, such as when performing DML operations on many tables. See also innodb_purge_batch_size.
- Command line: `--innodb-purge-threads=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `4`
- Range: `1` to `32`

`innodb_random_read_ahead`

- Description: Originally, random read-ahead was always set as an optimization technique, but was removed in MariaDB 5.5. `innodb_random_read_ahead` permits it to be re-instated if set to `1` (`0`) is default.
- Command line: `--innodb-random-read-ahead={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_read_ahead`

- Description: If set to `linear`, the default, XtraDB/InnoDB will automatically fetch remaining pages if there are enough within the same extent that can be accessed sequentially. If set to `none`, read-ahead is disabled. `random` has been removed and is now ignored, while `both` sets to both `linear` and `random`. Also see innodb_read_ahead_threshold for more control on read-aheads. Removed in MariaDB 10.0/XtraDB 5.6 and replaced by MySQL 5.6's innodb_random_read_ahead.
- Command line: `innodb-read-ahead=value`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `linear`
- Valid Values: `none`, `random`, `linear`, `both`
- Removed: MariaDB 10.0/XtraDB 5.6 - replaced by MySQL 5.6's innodb_random_read_ahead

`innodb_read_ahead_threshold`

- Description: Minimum number of pages InnoDB must read sequentially from an extent of 64 before initiating an asynchronous read for the following extent.
- Command line: `--innodb-read-ahead-threshold=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `56`
- Range: `0` to `64`

`innodb_read_io_threads`

- Description: Prior to MariaDB 10.5, this was simply the number of I/O threads for InnoDB reads. From MariaDB 10.5, asynchronous I/O functionality in the InnoDB Background Thread Pool replaces the old InnoDB I/O Threads. This variable is now multiplied by 256 to determine the maximum number of concurrent asynchronous I/O read requests that can be completed by the Background Thread Pool. The default is therefore 4*256 = 1024 conccurrent asynchronous read requests. You may on rare occasions need to reduce this default on Linux systems running multiple MariaDB servers to avoid exceeding system limits, or increase if spending too much time waiting on I/O requests.
- Command line: `--innodb-read-io-threads=#`
- Scope: Global
- Dynamic: Yes (>= MariaDB 10.11), No (<= MariaDB 10.10)
- Data Type: `numeric`
- Default Value: `4`
- Range: `1` to `64`

`innodb_read_only`

- Description: If set to `1` (`0` is default), the server are read-only. For use in distributed applications, data warehouses or read-only media.
- Command line: `--innodb-read-only={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`

- Default Value: `OFF`

`innodb_read_only_compressed`

- Description: If set (the default before MariaDB 10.6.6), ROW_FORMAT=COMPRESSED tables are read-only. This was intended to be the first step towards removing write support and deprecating the feature, but this plan has been abandoned.
- Command line: `--innodb-read-only-compressed`, `--skip-innodb-read-only-compressed`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF` (>= MariaDB 10.6.6), `ON` (<= MariaDB 10.6.5)
- Introduced: MariaDB 10.6.0

`innodb_recovery_stats`

- Description: If set to `1` (`0` is default) and recovery is necessary on startup, the server will write detailed recovery statistics to the error log at the end of the recovery process. This Percona XtraDB variable has not been ported to XtraDB 5.6.
- Command line: No
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.0

`innodb_recovery_update_relay_log`

- Description: If set to `1` (`0` is default), the relay log info file are overwritten on crash recovery if the information differs from the InnoDB record. Should not be used if multiple storage engine types are being replicated. Previously named `innodb_overwrite_relay_log_info`. Removed in MariaDB 10.0/XtraDB 5.6 and replaced by MySQL 5.6's `relay-log-recovery`
- Command line: `innodb-recovery-update-relay-log={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.0 - replaced by MySQL 5.6's `relay-log-recovery`

`innodb_replication_delay`

- Description: Time in milliseconds for the replica server to delay the replication thread if innodb_thread_concurrency is reached. Deprecated and ignored from MariaDB 10.5.5.
- Command line: `--innodb-replication-delay=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `4294967295`
- Deprecated: MariaDB 10.5.5

- Removed: MariaDB 10.6.0

`innodb_rollback_on_timeout`

- Description: InnoDB usually rolls back the last statement of a transaction that's been timed out (see innodb_lock_wait_timeout). If innodb_rollback_on_timeout is set to 1 (0 is default), InnoDB will roll back the entire transaction. Before MariaDB 5.5, rolling back the entire transaction was the default behavior.
- Command line: `--innodb-rollback-on-timeout`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `0`

`innodb_rollback_segments`

- Description: Specifies the number of rollback segments that XtraDB/InnoDB will use within a transaction (see undo log). Deprecated and replaced by innodb_undo_logs in MariaDB 10.0. Removed in MariaDB 10.5 as part of an InnoDB cleanup, as it makes sense to always create and use the maximum number of rollback segments. |
- Command line: `--innodb-rollback-segments=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `128`
- Range: `1` to `128`
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.5.0

`innodb_safe_truncate`

- Description: Use a backup-safe TRUNCATE TABLE implementation and crash-safe rename operations inside InnoDB. This is not compatible with hot backup tools other than mariadb-backup. Users who need to use such tools may set this to `OFF`.
- Command line: `--innodb-safe-truncate={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`
- Introduced: MariaDB 10.2.19
- Removed: MariaDB 10.3.0

`innodb_scrub_log`

- Description: Enable InnoDB redo log scrubbing. See Data Scrubbing. Deprecated and ignored from MariaDB 10.5.2, as never really worked (MDEV-13019 and MDEV-18370). If old log contents should be kept secret, then enabling innodb_encrypt_log or setting a smaller innodb_log_file_size could help.
- Command line: `--innodb-scrub-log`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`

- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_scrub_log_interval`

- Description: Used with Data Scrubbing in 10.1.3 only - replaced in 10.1.4 by innodb_scrub_log_speed. InnoDB redo log scrubbing interval in milliseconds.
- Command line: `--innodb-scrub-log-interval=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `56`
- Range: `0` to `50000`
- Introduced: MariaDB 10.1.3
- Removed: MariaDB 10.1.4

`innodb_scrub_log_speed`

- Description: InnoDB redo log scrubbing speed in bytes/sec. See Data Scrubbing. Deprecated and ignored from MariaDB 10.5.2.
- Command line: `--innodb-scrub-log-speed=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `256`
- Range: `1` to `50000`
- Deprecated: MariaDB 10.5.2
- Removed: MariaDB 10.6.0

`innodb_sched_priority_cleaner`

- Description: Set a thread scheduling priority for cleaner and least-recently used (LRU) manager threads. The range from `0` to `39` corresponds in reverse order to Linux nice values of `-20` to `19`. So `0` is the lowest priority (Linux nice value `19`) and `39` is the highest priority (Linux nice value `-20`). XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-sched-priority-cleaner=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `19`
- Range: `0` to `39`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_show_locks_held`

- Description: Specifies the number of locks held for each InnoDB transaction to be displayed in SHOW ENGINE INNODB STATUS output. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.

- Command line: `innodb-show-locks-held=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `10`
- Range: `0` to `1000`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_show_verbose_locks`

- Description: If set to `1`, and innodb_status_output_locks is also ON, the traditional InnoDB behavior is followed and locked records are shown in INFORMATION_SCHEMA.INNODB_METRICS output. If set to `0`, the default, only high-level information about the lock is shown. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-show-verbose-locks=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `1`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_simulate_comp_failures`

- Description: Simulate compression failures. Used for testing robustness against random compression failures. XtraDB only.
- Command line: None
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `99`

`innodb_snapshot_isolation`

- Description: Whether or not to use snapshot isolation (write/write conflict detection within InnoDB).
  If enabled (set to `ON`), an error `DB_RECORD_CHANGED` (`HA_ERR_RECORD_CHANGED`, `ER_CHECKREAD`) is raised if an attempt is made to acquire a lock on a record that does not exist in the current read view. This error is treated in the same way as a deadlock, and the transaction is rolled back. This affects the default isolation level, REPEATABLE READ.
  In MariaDB 11.8 and later, changes to snapshot handling may affect how conflicts are detected in transactions that use the Repeatable Read isolation level. Specifically, `DELETE` and `UPDATE` statements can cause a rollback of the transaction, and return with ERROR 1020. This occurs when a transaction tries to modify rows using a snapshot that is inconsistent with the database's current state as a result of simultaneous modifications. In other words, this variable is designed to prevent non-repeatable reads and anomalies (like lost updates) by rejecting `UPDATE` or `DELETE` operations on rows that were modified by a concurrent transaction after the current transaction's snapshot was taken.

- Command line: `--innodb-snapshot-isolation={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON` (>= MariaDB 11.6.2), `OFF` (<= MariaDB 11.6.1)
- Introduced: MariaDB 10.6.18, MariaDB 10.11.8, MariaDB 11.0.6, MariaDB 11.1.5, MariaDB 11.2.4, MariaDB 11.4.2

`innodb_sort_buffer_size`

- Description: Size of the sort buffers used for sorting data when an InnoDB index is created, as well as the amount by which the temporary log file is extended during online DDL operations to record concurrent writes. The larger the setting, the fewer merge phases are required between buffers while sorting. When a CREATE TABLE or ALTER TABLE creates a new index, three buffers of this size are allocated, as well as pointers for the rows in the buffer.
- Command line: `--innodb-sort-buffer-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `1048576` (1M)
- Range: `65536` to `67108864`

`innodb_spin_wait_delay`

- Description: Maximum delay (not strictly corresponding to a time unit) between spin lock polls. Default changed from `6` to `4` in MariaDB 10.3.5, as this was verified to give the best throughput by OLTP update index and read-write benchmarks on Intel Broadwell (2/20/40) and ARM (1/46/46).
- Command line: `--innodb-log-spin-wait-delay=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `4` (>= MariaDB 10.3.5), `6` (<= MariaDB 10.3.4)
- Range: `0` to `4294967295`

`innodb_stats_auto_recalc`

- Description: If set to `1` (the default), persistent statistics are automatically recalculated when the table changes significantly (more than 10% of the rows). Affects tables created or altered with STATS_PERSISTENT=1 (see CREATE TABLE), or when innodb_stats_persistent is enabled. innodb_stats_persistent_sample_pages determines how much data to sample when recalculating. See InnoDB Persistent Statistics.
- Command line: `--innodb-stats-auto-recalc={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_stats_auto_update`

- Description: If set to `0` (`1` is default), index statistics will not be automatically calculated except when an ANALYZE TABLE is run, or the table is first opened. Replaced by innodb_stats_auto_recalc in MariaDB

10.0/XtraDB 5.6.

- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `1`
- Removed: MariaDB 10.0 - replaced by innodb_stats_auto_recalc.

`innodb_stats_include_delete_marked`

- Description: Include delete marked records when calculating persistent statistics.
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_stats_method`

- Description: Determines how NULLs are treated for InnoDB index statistics purposes.
  - `nulls_equal`: The default, all NULL index values are treated as a single group. This is usually fine, but if you have large numbers of NULLs the average group size is slanted higher, and the optimizer may miss using the index for ref accesses when it would be useful.
  - `nulls_unequal`: The opposite approach to `nulls_equal` is taken, with each NULL forming its own group of one. Conversely, the average group size is slanted lower, and the optimizer may use the index for ref accesses when not suitable.
  - `nulls_ignored`: Ignore NULLs altogether from index group calculations.
  - See also Index Statistics, aria_stats_method and myisam_stats_method.
- Command line: `--innodb-stats-method=name`
- Scope: Global
- Dynamic: Yes
- Data Type: `enumeration`
- Default Value: `nulls_equal`
- Valid Values: `nulls_equal`, `nulls_unequal`, `nulls_ignored`

`innodb_stats_modified_counter`

- Description: The number of rows modified before we calculate new statistics. If set to `0`, the default, current limits are used.
- Command line: `--innodb-stats-modified-counter=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `18446744073709551615`

`innodb_stats_on_metadata`

- Description: If set to `ON`, XtraDB/InnoDB updates statistics when accessing the INFORMATION_SCHEMA.TABLES or INFORMATION_SCHEMA.STATISTICS tables, and when running metadata statements such as SHOW INDEX or SHOW TABLE STATUS. If set to `OFF` (the default), statistics are

not updated at those times, which can reduce the access time for large schemas, as well as make execution plans more stable.

- Command line: `--innodb-stats-on-metadata`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_stats_persistent`

- Description: ANALYZE TABLE produces index statistics, and this setting determines whether they are stored on disk, or be required to be recalculated more frequently, such as when the server restarts. This information is stored for each table, and can be set with the STATS_PERSISTENT clause when creating or altering tables (see CREATE TABLE). See InnoDB Persistent Statistics.
- Command line: `--innodb-stats-persistent={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_stats_persistent_sample_pages`

- Description: Number of index pages sampled when estimating cardinality and statistics for indexed columns. Increasing this value will increases index statistics accuracy, but use more I/O resources when running ANALYZE TABLE. See InnoDB Persistent Statistics.
- Command line: `--innodb-stats-persistent-sample-pages=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `20`

`innodb_stats_sample_pages`

- Description: Gives control over the index distribution statistics by determining the number of index pages to sample. Higher values produce more disk I/O, but, especially for large tables, produce more accurate statistics and therefore make more effective use of the query optimizer. Lower values than the default are not recommended, as the statistics can be quite inaccurate.
  - If innodb_stats_traditional is enabled, then the exact number of pages configured by this system variable are sampled for statistics.
  - If innodb_stats_traditional is disabled, then the number of pages to sample for statistics is calculated using a logarithmic algorithm, so the exact number can change depending on the size of the table. This means that more samples may be used for larger tables.
  - If persistent statistics are enabled, then the innodb_stats_persistent_sample_pages system variable applies instead. persistent statistics are enabled with the innodb_stats_persistent system variable.
  - This system variable has been deprecated. The innodb_stats_transient_sample_pages system variable should be used instead.
- Command line: `--innodb-stats-sample-pages=#`
- Scope: Global
- Dynamic: Yes

- Data Type: `numeric`
- Default Value: `8`
- Range: `1` to `2^64-1`
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.5.0

`innodb_stats_traditional`

- Description: This system variable affects how the number of pages to sample for transient statistics is determined, in particular how innodb_stats_transient_sample_pages is used.
  - If innodb_stats_traditional is enabled, then the exact number of pages configured by the system variable are sampled for statistics.
  - If innodb_stats_traditional is disabled, then the number of pages to sample for statistics is calculated using a logarithmic algorithm, so the exact number can change depending on the size of the table. This means that more samples may be used for larger tables.
  - This system variable does not affect the calculation of persistent statistics.
- Command line: `--innodb-stats-traditional={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_stats_transient_sample_pages`

- Description: Gives control over the index distribution statistics by determining the number of index pages to sample. Higher values produce more disk I/O, but, especially for large tables, produce more accurate statistics and therefore make more effective use of the query optimizer. Lower values than the default are not recommended, as the statistics can be quite inaccurate.
  - If innodb_stats_traditional is enabled, then the exact number of pages configured by this system variable are sampled for statistics.
  - If innodb_stats_traditional is disabled, then the number of pages to sample for statistics is calculated using a logarithmic algorithm, so the exact number can change depending on the size of the table. This means that more samples may be used for larger tables.
  - If persistent statistics are enabled, then the innodb_stats_persistent_sample_pages system variable applies instead. persistent statistics are enabled with the innodb_stats_persistent system variable.
- Command line: `--innodb-stats-transient-sample-pages=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `8`
- Range: `1` to `2^64-1`

`innodb_stats_update_need_lock`

- Description: Setting to `0` (`1` is default) may help reduce contention of the `&dict_operation_lock`, but also disables the Data_free option in SHOW TABLE STATUS. This Percona XtraDB variable has not been ported to XtraDB 5.6.
- Scope: Global
- Dynamic: Yes

- Data Type: `boolean`
- Default Value: `1`
- Removed: MariaDB 10.0/XtraDB 5.6

`innodb_status_output`

- Description: Enable InnoDB monitor output to the error log.
- Command line: `--innodb-status-output={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_status_output_locks`

- Description: Enable InnoDB lock monitor output to the error log and SHOW ENGINE INNODB STATUS. Also requires innodb_status_output=ON to enable output to the error log.
- Command line: `--innodb-status-output-locks={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_strict_mode`

- Description: If set to `1` (the default), InnoDB will return errors instead of warnings in certain cases, similar to strict SQL mode. See InnoDB Strict Mode for details.
- Command line: `--innodb-strict-mode={0|1}`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_support_xa`

- Description: If set to `1`, the default, XA transactions are supported. XA support ensures data is written to the binary log in the same order to the actual database, which is critical for replication and disaster recovery, but comes at a small performance cost. If your database is set up to only permit one thread to change data (for example, on a replication replica with only the replication thread writing), it is safe to turn this option off. Removed in MariaDB 10.3, XA transactions are always supported.
- Command line: `--innodb-support-xa`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.2
- Removed: MariaDB 10.3.0

`innodb_sync_array_size`

- Description: By default `1`, can be increased to split internal thread co-ordinating, giving higher concurrency when there are many waiting threads.
- Command line: `--innodb-sync-array-size=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `1`
- Range: `1` to `1024`
- Removed: MariaDB 10.6.0

`innodb_sync_spin_loops`

- Description: The number of times a thread waits for an InnoDB mutex to be freed before the thread is suspended.
- Command line: `--innodb-sync-spin-loops=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `30`
- Range: `0` to `4294967295`

`innodb_table_locks`

- Description: If autocommit is set to `0` (`1` is default), setting innodb_table_locks to `1`, the default, will cause InnoDB to lock a table internally upon a LOCK TABLE.
- Command line: `--innodb-table-locks`
- Scope: Global, Session
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`

`innodb_thread_concurrency`

- Description: Once this number of threads is reached (excluding threads waiting for locks), XtraDB/InnoDB will place new threads in a wait state in a first-in, first-out queue for execution, in order to limit the number of threads running concurrently. A setting of `0`, the default, permits as many threads as necessary. A suggested setting is twice the number of CPU's plus the number of disks. Deprecated and ignored from MariaDB 10.5.5.
- Command line: `--innodb-thread-concurrency=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `0`
- Range: `0` to `1000`
- Deprecated: MariaDB 10.5.5
- Removed: MariaDB 10.6.0

`innodb_thread_concurrency_timer_based`

- Description: If set to `1`, thread concurrency are handled in a lock-free timer-based manner rather than the default mutex-based method. Depends on atomic op builtins being available. This Percona XtraDB variable has not been ported to XtraDB 5.6.
- Command line: `innodb-thread-concurrency-timer-based={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Removed: MariaDB 10.0/XtraDB 5.6

`innodb_thread_sleep_delay`

- Description: Time in microseconds that InnoDB threads sleep before joining the queue. Setting to `0` disables sleep. Deprecated and ignored from MariaDB 10.5.5
- Command line: `--innodb-thread-sleep-delay=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value:
  - `0` (>= MariaDB 10.5.5.)
  - `10000` (<= MariaDB 10.5.4)
- Range: `0` to `1000000`
- Deprecated: MariaDB 10.5.5
- Removed: MariaDB 10.6.0

`innodb_temp_data_file_path`

- Description: Path where to store data for InnoDB temporary tables. Argument is `filename:size` followed by options separated by ':' Multiple paths can be given separated by ';' A file size is specified (with K for kilobytes, M for megabytes and G for gigabytes). Also whether or not to `autoextend` the data file, `max` size and whether or not to autoshrink on startup may also be specified.
- Command line: `--innodb-temp-data-file-path=path`
- Scope: Global
- Dynamic: No
- Data Type: `string`
- Default Value: `ibtmp1:12M:autoextend`
- Documentation & examples: innodb-temporary-tablespaces

`innodb_tmpdir`

- Description: Allows an alternate location to be set for temporary non-tablespace files. If not set (the default), files are created in the usual tmpdir location.
  Alternate location must be outside of `datadir`
- Command line: `--innodb-tmpdir=path`
- Scope: Global
- Dynamic: Yes
- Data Type: `string`

- Default Value: Empty

`innodb_track_changed_pages`

- Description: For faster incremental backup with Xtrabackup, XtraDB tracks pages with changes written to them according to the XtraDB redo log and writes the information to special changed page bitmap files. This read-only variable is used for controlling this feature. See also innodb_max_changed_pages and innodb_max_bitmap_file_size. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-track-changed-pages={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.2.6

`innodb_track_redo_log_now`

- Description: Available on debug builds only. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-track-redo-log-now={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.2.6

`innodb_truncate_temporary_tablespace_now`

- Description: Set to ON to shrink the temporary tablespace.
- Command line: `innodb-truncate-temporary-tablespace-now={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`
- Introduced: MariaDB 11.3.0

`innodb_undo_directory`

- Description: Path to the directory (relative or absolute) that InnoDB uses to create separate tablespaces for the undo logs. `.` (the default value before 10.2.2) leaves the undo logs in the same directory as the other log files. From MariaDB 10.2.2, the default value is NULL, and if no path is specified, undo tablespaces are created in the directory defined by datadir. Use together with innodb_undo_logs and innodb_undo_tablespaces. Undo logs are most usefully placed on a separate storage device.
- Command line: `--innodb-undo-directory=name`
- Scope: Global
- Dynamic: No
- Data Type: `string`
- Default Value: NULL

`innodb_undo_log_truncate`

- Description: When enabled, innodb_undo_tablespaces that are larger than innodb_max_undo_log_size are marked for truncation. See also innodb_purge_rseg_truncate_frequency. Enabling this setting may cause stalls during heavy write workloads.
- Command line: `--innodb-undo-log-truncate[={0|1}]`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `OFF`

`innodb_undo_logs`

- Description: Specifies the number of rollback segments that XtraDB/InnoDB will use within a transaction (or the number of active undo logs). By default set to the maximum, `128`, it can be reduced to avoid allocating unneeded rollback segments. See the Innodb_available_undo_logs status variable for the number of undo logs available. See also innodb_undo_directory and innodb_undo_tablespaces. Replaced innodb_rollback_segments in MariaDB 10.0. The Information Schema XTRADB_RSEG Table contains information about the XtraDB rollback segments. Deprecated and ignored in MariaDB 10.5.0, as it always makes sense to use the maximum number of rollback segments.
- Command line: `--innodb-undo-logs=#`
- Scope: Global
- Dynamic: Yes
- Data Type: `numeric`
- Default Value: `128`
- Range: `0` to `128`
- Deprecated: MariaDB 10.5.0
- Removed: MariaDB 10.6.0

`innodb_undo_tablespaces`

- Description: Number of tablespaces files used for dividing up the undo logs. Zero (the default before MariaDB 11.0) means that undo logs are all part of the system tablespace, which contains one undo tablespace more than the `innodb_undo_tablespaces` setting. A value of 1 is reset to 0 as 2 or more are needed for separate tablespaces. When the undo logs can grow large, splitting them over multiple tablespaces will reduce the size of any single tablespace. Until MariaDB 10.11.1, must be set before InnoDB is initialized, or else MariaDB will fail to start, with an error saying that `InnoDB did not find the expected number of undo tablespaces`. The files are created in the directory specified by innodb_undo_directory, and are named `undoN`, N being an integer. The default size of an undo tablespace is 10MB.From MariaDB 11.0, multiple undo tablespaces are enabled by default, and the default is changed to 3 so that the space occupied by possible bursts of undo log records can be reclaimed after innodb_undo_log_truncate is set. Before MariaDB 10.6, innodb_undo_logs must have a non-zero setting for `innodb_undo_tablespaces` to take effect.
- Command line: `--innodb-undo-tablespaces=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `3` (>= MariaDB 11.0), `0` (<= MariaDB 10.11)
- Range: `0`, or `2` to `95`

`innodb_use_atomic_writes`

- Description: Implement atomic writes on supported SSD devices. See atomic write support for other variables affected when this is set.
- Command line: `innodb-use-atomic-writes={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`

`innodb_use_fallocate`

- Description: Preallocate files fast, using operating system functionality. On POSIX systems, posix_fallocate system call is used.
  - Automatically set to `1` when innodb_use_atomic_writes is set - see FusionIO DirectFS atomic write support.
  - See InnoDB Page Compression: Saving Storage Space with Sparse Files for more information.
- Command line: `innodb-use-fallocate={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.2.5 (treated as if `ON`)
- Removed: MariaDB 10.3.0

`innodb_use_global_flush_log_at_trx_commit`

- Description: Determines whether a user can set the variable innodb_flush_log_at_trx_commit. If set to `1`, a user cannot reset the value with a SET command, while if set to `1`, a user can reset the value of `innodb_flush_log_at_trx_commit`. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `innodb-use-global-flush-log-at-trx_commit={0|1}`
- Scope: Global
- Dynamic: Yes
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_use_mtflush`

- Description: Whether to enable Multi-Threaded Flush operations.
  For more information, see Fusion.
  - InnoDB's multi-thread flush feature was deprecated in MariaDB 10.2.9 and removed from MariaDB 10.3.2. In later versions of MariaDB, use innodb_page_cleaners system variable instead.
  - See InnoDB Page Flushing: Page Flushing with Multi-threaded Flush Threads for more information.
- Command line: `--innodb-use-mtflush={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`

- Default Value: `OFF`
- Deprecated: MariaDB 10.2.9
- Removed: MariaDB 10.3.2

`innodb_use_native_aio`

- Description: For Linux systems only, specified whether to use Linux's asynchronous I/O subsystem. Set to `ON` by default, it may be changed to `0` at startup if InnoDB detects a problem, or from MariaDB 10.6.5/MariaDB 10.7.1, if a 5.11 - 5.15 Linux kernel is detected, to avoid an io-uring bug/incompatibility (MDEV-26674). MariaDB-10.6.6/MariaDB-10.7.2 and later also consider 5.15.3+ as a fixed kernel and default to `ON`. To really benefit from the setting, the files should be opened in O_DIRECT mode (innodb_flush_method=O_DIRECT, default from MariaDB 10.6), to bypass the file system cache. In this way, the reads and writes can be submitted with DMA, using the InnoDB buffer pool directly, and no processor cycles need to be used for copying data.
- Command line: `--innodb-use-native-aio={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`

`innodb_use_purge_thread`

- Description: Usually with InnoDB, data changed by a transaction is written to an undo space to permit read consistency, and freed when the transaction is complete. Many, or large, transactions, can cause the main tablespace to grow dramatically, reducing performance. This option, introduced in XtraDB 5.1 and removed for 5.5, allows multiple threads to perform the purging, resulting in slower, but much more stable performance.
- Command line: `--innodb-use-purge-thread=#`
- Scope: Global
- Dynamic: No
- Data Type: `numeric`
- Default Value: `1`
- Range: `0` to `32`
- Removed: XtraDB 5.5

`innodb_use_stacktrace`

- Description: If set to `ON` (`OFF` is default), a signal handler for SIGUSR2 is installed when the InnoDB server starts. When a long semaphore wait is detected at sync/sync0array.c, a SIGUSR2 signal is sent to the waiting thread and thread that has acquired the RW-latch. For both threads a full stacktrace is produced as well as if possible. XtraDB only. Added as a deprecated and ignored option in MariaDB 10.2.6 (which uses InnoDB as default instead of XtraDB) to allow for easier upgrades.
- Command line: `--innodb-use-stacktrace={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `OFF`
- Deprecated: MariaDB 10.2.6
- Removed: MariaDB 10.3.0

`innodb_use_sys_malloc`

- Description: If set the `1`, the default, XtraDB/InnoDB will use the operating system's memory allocator. If set to `0` it will use its own. Deprecated in MariaDB 10.0 and removed in MariaDB 10.2 along with InnoDB's internal memory allocator.
- Command line: `--innodb-use-sys-malloc={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.0
- Removed: MariaDB 10.2.2

`innodb_use_sys_stats_table`

- Description: If set to `1` (`0` is default), XtraDB will use the SYS_STATS system table for extra table index statistics. When a table is opened for the first time, statistics will then be loaded from SYS_STATS instead of sampling the index pages. Statistics are designed to be maintained only by running an ANALYZE TABLE. Replaced by MySQL 5.6's Persistent Optimizer Statistics.
- Command line: `innodb-use-sys-stats-table={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `0`
- Removed: MariaDB 10.0/XtraDB 5.6

`innodb_use_trim`

- Description: Use trim to free up space of compressed blocks.
  - See InnoDB Page Compression: Saving Storage Space with Sparse Files for more information.
- Command line: `--innodb-use-trim={0|1}`
- Scope: Global
- Dynamic: No
- Data Type: `boolean`
- Default Value: `ON`
- Deprecated: MariaDB 10.2.4
- Removed: MariaDB 10.3.0

`innodb_version`

- Description: InnoDB version number. From MariaDB 10.3.7, as the InnoDB implementation in MariaDB has diverged from MySQL, the MariaDB version is instead reported. For example, the InnoDB version reported in MariaDB 10.1 (which is based on MySQL 5.6) included encryption and variable-size page compression before MySQL 5.7 introduced them. MariaDB 10.2 (based on MySQL 5.7) introduced persistent AUTO_INCREMENT (MDEV-6076) in a GA release before MySQL 8.0. MariaDB 10.3 (based on MySQL 5.7) introduced instant ADD COLUMN (MDEV-11369) before MySQL.
- Scope: Global
- Dynamic: No
- Data Type: `string`
- Removed: MariaDB 10.10

`innodb_write_io_threads`

- Description: Prior to MariaDB 10.5, this was simply the number of I/O threads for InnoDB writes. From MariaDB 10.5, asynchronous I/O functionality in the InnoDB Background Thread Pool replaces the old InnoDB I/O Threads. This variable is now multiplied by 256 to determine the maximum number of concurrent asynchronous I/O write requests that can be completed by the Background Thread Pool. The default is therefore 4*256 = 1024 conccurrent asynchronous write requests. You may on rare occasions need to reduce this default on Linux systems running multiple MariaDB servers to avoid exceeding system limits, or increase if spending too much time waiting on I/O requests.
- Command line: `--innodb-write-io-threads=#`
- Scope: Global
- Dynamic: Yes (>= MariaDB 10.11), No (<= MariaDB 10.10)
- Data Type: `numeric`
- Default Value: `4`
- Range: `1` to `64`

InnoDB Versions

> **Warning:**
>
> This page is outdated. It's left in place because release notes for old MariaDB versions refer to it (MariaDB < 10.3).

The InnoDB implementation has diverged substantially from the InnoDB in MySQL. Therefore, in these versions, the InnoDB version is no longer associated with a MySQL release version.

The default InnoDB implementation is based on InnoDB from MySQL 5.7. See Why MariaDB uses InnoDB instead of XtraDB from MariaDB 10.2 for more information.

Note

XtraDB is a performance enhanced fork of InnoDB. For compatibility reasons, the system variables still retain their original `innodb` prefixes. If the documentation says that something applies to InnoDB, then it usually also applies to the XtraDB fork, unless explicitly stated otherwise. In these versions, it is still possible to use InnoDB instead of XtraDB. See Using InnoDB instead of XtraDB for more information.

Divergences

Some examples of divergences between MariaDB's InnoDB and MySQL's InnoDB are:

- MariaDB 10.1 (which is based on MySQL 5.6) included encryption and variable-size page compression before MySQL 5.7 introduced them.
- MariaDB 10.2 (based on MySQL 5.7) introduced persistent AUTO_INCREMENT (MDEV-6076) in a GA release before MySQL 8.0.
- MariaDB 10.3 (based on MySQL 5.7) introduced instant ADD COLUMN (MDEV-11369) before MySQL.

InnoDB Versions Included in MariaDB Releases

MariaDB 10.3

InnoDB Version	Introduced
No longer reported	MariaDB 10.3.7
InnoDB 5.7.20	MariaDB 10.3.3

InnoDB Version	Introduced
InnoDB 5.7.19	MariaDB 10.3.1
InnoDB 5.7.14	MariaDB 10.3.0

MariaDB 10.2

InnoDB Version	Introduced
InnoDB 5.7.29	MariaDB 10.2.33
InnoDB 5.7.23	MariaDB 10.2.17
InnoDB 5.7.22	MariaDB 10.2.15
InnoDB 5.7.21	MariaDB 10.2.13
InnoDB 5.7.20	MariaDB 10.2.10
InnoDB 5.7.19	MariaDB 10.2.8
InnoDB 5.7.18	MariaDB 10.2.7
InnoDB 5.7.14	MariaDB 10.2.2

MariaDB 10.1

InnoDB Version	Introduced
InnoDB 5.6.49	MariaDB 10.1.46
InnoDB 5.6.47	MariaDB 10.1.44
InnoDB 5.6.44	MariaDB 10.1.39
InnoDB 5.6.42	MariaDB 10.1.37
InnoDB 5.6.39	MariaDB 10.1.31

MariaDB Enterprise Server InnoDB Background Thread Pool

Overview

Starting with MariaDB Enterprise Server 10.5 and MariaDB Community Server 10.5, InnoDB uses the InnoDB Background Thread Pool to perform internal operations in the background. In previous versions, the internal operations were performed by dedicated threads. By using the InnoDB Background Thread Pool instead of many dedicated threads, InnoDB can reduce context switching and use system resources more effectively.

The InnoDB Background Thread Pool performs internal operations in multiple categories: **tasks**, **timers**, and **asynchronous I/O**.

Tasks are used to perform internal operations that are triggered by some event. In ES 10.5 and later and CS 10.5 and later, the following threads have been replaced by **tasks** with the InnoDB Background Thread Pool:

- The InnoDB Buffer Pool Resize Thread
- The InnoDB Buffer Pool Dump Thread
- The InnoDB Full-Text Search (FTS) Optimization Thread

Timers are used to perform internal operations that are triggered periodically. In ES 10.5 and later and CS 10.5 and later, the following threads have been replaced by **timers** with the InnoDB Background Thread Pool:

- The InnoDB Master Thread
- The InnoDB Defragmentation Thread
- The InnoDB Monitor Thread
- The InnoDB Error Monitor Thread

Asynchronous I/O is used to read from and write to disk asynchronously. In ES 10.5 and later and CS 10.5 and later, the following threads have been replaced by **asynchronous I/O** with the InnoDB Background Thread Pool:

- The InnoDB I/O Threads

Feature Summary

Feature	Detail	Resources
Thread Pool	InnoDB Background Thread Pool	
Storage Engine	InnoDB	
Purpose	Handles background tasks for InnoDB	
Availability	• ES 10.5+ • CS 10.5+	MariaDB Enterprise Server

MariaDB Enterprise Server InnoDB I/O Threads

Overview

Starting with MariaDB Enterprise Server 10.5 and MariaDB Community Server 10.5, the InnoDB I/O Threads were replaced by the asynchronous I/O functionality in the InnoDB Background Thread Pool.

Feature Summary

Feature	Detail	Resources
Thread	InnoDB I/O Threads	
Storage Engine	InnoDB	
Purpose	Reading data from disk / Writing data to disk	
Availability		MariaDB Enterprise Server
Quantity	Set by innodb_read_io_threads and innodb_write_io_threads	Configure the InnoDB I/O Threads

Basic Configuration

```
[mariadb]
...
innodb_read_io_threads=8
innodb_write_io_threads=8
```

```
SET GLOBAL innodb_read_io_threads=8;
SET GLOBAL innodb_write_io_threads=8;

SHOW GLOBAL VARIABLES
   LIKE 'innodb_%_io_threads';
```

```
+-------------------------+-------+
| Variable_name           | Value |
+-------------------------+-------+
| innodb_read_io_threads  | 8     |
| innodb_write_io_threads | 8     |
+-------------------------+-------+

InnoDB Online DDL Overview

InnoDB tables support online DDL, which permits concurrent DML and uses optimizations to avoid unnecessary table copying.

The ALTER TABLE statement supports two clauses that are used to implement online DDL:

- ALGORITHM - This clause controls how the DDL operation is performed.
- LOCK - This clause controls how much concurrency is allowed while the DDL operation is being performed.

Alter Algorithms

InnoDB supports multiple algorithms for performing DDL operations. This offers a significant performance improvement over previous versions. The supported algorithms are:

- `DEFAULT` - This implies the default behavior for the specific operation.
- `COPY`
- `INPLACE`
- `NOCOPY`
- `INSTANT`

Specifying an Alter Algorithm

The set of alter algorithms can be considered as a hierarchy. The hierarchy is ranked in the following order, with *least efficient* algorithm at the top, and *most efficient* algorithm at the bottom:

- `COPY`
- `INPLACE`
- `NOCOPY`
- `INSTANT`

When a user specifies an alter algorithm for a DDL operation, MariaDB does not necessarily use that specific algorithm for the operation. It interprets the choice in the following way:

- If the user specifies `COPY`, then InnoDB uses the `COPY` algorithm.
- If the user specifies any other algorithm, then InnoDB interprets that choice as the least efficient algorithm that the user is willing to accept. This means that if the user specifies `INPLACE`, then InnoDB will use the most efficient algorithm supported by the specific operation from the set (`INPLACE`, `NOCOPY`, `INSTANT`). Likewise, if the user specifies `NOCOPY`, then InnoDB will use the most efficient algorithm supported by the specific operation from the set (`NOCOPY`, `INSTANT`).

There is also a special value that can be specified:

- If the user specifies `DEFAULT`, then InnoDB uses its default choice for the operation. The default choice is to use the most efficient algorithm supported by the operation. The default choice will also be used if no algorithm is specified. Therefore, if you want InnoDB to use the most efficient algorithm supported by an operation, then you usually do not have to explicitly specify any algorithm at all.

Specifying an Alter Algorithm Using the ALGORITHM Clause

InnoDB supports the ALGORITHM clause.

The ALGORITHM clause can be used to specify the *least efficient* algorithm that the user is willing to accept. It is supported by the ALTER TABLE and CREATE INDEX statements.

For example, if a user wanted to add a column to a table, but only if the operation used an algorithm that is at least as efficient as the `INPLACE`, then they could execute the following:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

ALTER TABLE tab ADD COLUMN c VARCHAR(50), ALGORITHM=INPLACE;
```

The above operation should use the `INSTANT` algorithm, because the `ADD COLUMN` operation supports the `INSTANT` algorithm, and the `INSTANT` algorithm is more efficient than the `INPLACE` algorithm.

Specifying an Alter Algorithm Using System Variables

The alter_algorithm system variable can be used to pick the *least efficient* algorithm that the user is willing to accept.

For example, if a user wanted to add a column to a table, but only if the operation used an algorithm that is at least as efficient as the `INPLACE`, then they could execute the following:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD COLUMN c VARCHAR(50);
```

The above operation would actually use the `INSTANT` algorithm, because the `ADD COLUMN` operation supports the `INSTANT` algorithm, and the `INSTANT` algorithm is more efficient than the `INPLACE` algorithm.
<>

Supported Alter Algorithms

The supported algorithms are described in more details below.

DEFAULT Algorithm

The default behavior, which occurs if `ALGORITHM=DEFAULT` is specified, or if `ALGORITHM` is not specified at all, usually only makes a copy if the operation doesn't support being done in-place at all. In this case, the *most efficient* available algorithm will usually be used.

This means that, if an operation supports the `INSTANT` algorithm, then it will use that algorithm by default. If an operation does not support the `INSTANT` algorithm, but it does support the `NOCOPY` algorithm, then it will use that algorithm by default. If an operation does not support the `NOCOPY` algorithm, but it does support the `INPLACE` algorithm, then it will use that algorithm by default.

COPY Algorithm

The `COPY` algorithm refers to the original ALTER TABLE algorithm.

When the `COPY` algorithm is used, MariaDB essentially does the following operations:

```
-- Create a temporary table with the new definition
CREATE TEMPORARY TABLE tmp_tab (
...
);

-- Copy the data from the original table
INSERT INTO tmp_tab
   SELECT * FROM original_tab;

-- Drop the original table
DROP TABLE original_tab;

-- Rename the temporary table, so that it replaces the original one
RENAME TABLE tmp_tab TO original_tab;
```

This algorithm is very inefficient, but it is generic, so it works for all storage engines.

If the `COPY` algorithm is specified with the ALGORITHM clause or with the alter_algorithm system variable, then the `COPY` algorithm are used even if it is not necessary. This can result in a lengthy table copy. If multiple ALTER TABLE operations are required that each require the table to be rebuilt, then it is best to specify all operations in a single ALTER TABLE statement, so that the table is only rebuilt once.

Using the COPY Algorithm with InnoDB

If the `COPY` algorithm is used with an InnoDB table, then the following statements apply:

- The table are rebuilt using the current values of the innodb_file_per_table, innodb_file_format, and innodb_default_row_format system variables.
- The operation will have to create a temporary table to perform the table copy. This temporary table are in the same directory as the original table, and it's file name are in the format `#sql${PID}_${THREAD_ID}_${TMP_TABLE_COUNT}`, where `${PID}` is the process ID of `mysqld`, `${THREAD_ID}` is the connection ID, and `${TMP_TABLE_COUNT}` is the number of temporary tables that the connection has open. Therefore, the datadir may contain files with file names like `#sql1234_12_1.ibd`.
- The operation inserts one record at a time into each index, which is very inefficient.
- InnoDB does not use a sort buffer.
- The table copy operation creates a lot fewer InnoDB undo log writes. See MDEV-11415 for more information.
- The table copy operation creates a lot of InnoDB redo log writes.

INPLACE Algorithm

The `COPY` algorithm can be incredibly slow, because the whole table has to be copied and rebuilt. The `INPLACE` algorithm was introduced as a way to avoid this by performing operations in-place and avoiding the table copy and rebuild, when possible.

When the `INPLACE` algorithm is used, the underlying storage engine uses optimizations to perform the operation while avoiding the table copy and rebuild. However, `INPLACE` is a bit of a misnomer, since some operations may still require the table to be rebuilt for some storage engines. Regardless, several operations can be performed without a full copy of the table for some storage engines.

A more accurate name for the algorithm would have been the `ENGINE` algorithm, since the storage engine decides how to implement the algorithm.

If an ALTER TABLE operation supports the `INPLACE` algorithm, then it can be performed using optimizations by the underlying storage engine, but it may rebuilt.

If the `INPLACE` algorithm is specified with the ALGORITHM clause or with the alter_algorithm system variable and if the ALTER TABLE operation does not support the `INPLACE` algorithm, then an error are raised:

```
SET SESSION alter_algorithm='INPLACE';

ALTER TABLE tab MODIFY COLUMN c INT;
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

In this case, raising an error is preferable, if the alternative is for the operation to make a copy of the table, and perform unexpectedly slowly.

Using the INPLACE Algorithm with InnoDB

If the `INPLACE` algorithm is used with an InnoDB table, then the following statements apply:

- The operation might have to write sort files in the directory defined by the innodb_tmpdir system variable.
- The operation might also have to write a temporary log file to track data changes by DML queries executed during the operation. The maximum size for this log file is configured by the innodb_online_alter_log_max_size system variable.
- Some operations require the table to be rebuilt, even though the algorithm is inaccurately called "in-place". This includes operations such as adding or dropping columns, adding a primary key, changing a column to NULL, etc.
- If the operation requires the table to be rebuilt, then the operation might have to create temporary tables.

    - It may have to create a temporary intermediate table for the actual table rebuild operation.
        - This temporary table are in the same directory as the original table, and it's file name are in the format `#sql${PID}_${THREAD_ID}_${TMP_TABLE_COUNT}`, where `${PID}` is the process ID of `mysqld`, `${THREAD_ID}` is the connection ID, and `${TMP_TABLE_COUNT}` is the number of temporary tables that the connection has open. Therefore, the datadir may contain files with file names like `#sql1234_12_1.ibd`.
    - When it replaces the original table with the rebuilt table, it may also have to rename the original table using a temporary table name.
        - The innodb_safe_truncate system variable is set to `OFF`, then the format will actually be `#sql-ib${TABLESPACE_ID}-${RAND}`, where `${TABLESPACE_ID}` is the table's tablespace ID within InnoDB and `${RAND}` is a randomly initialized number. Therefore, the datadir may contain files with file names like `#sql-ib230291-1363966925.ibd`.
- The storage needed for the above items can add up to the size of the original table, or more in some cases.
- Some operations are instantaneous, if they only require the table's metadata to be changed. This includes operations such as renaming a column, changing a column's DEFAULT value, etc.

Operations Supported by InnoDB with the `INPLACE` Algorithm

With respect to the allowed operations, the `INPLACE` algorithm supports a subset of the operations supported by the `COPY` algorithm, and it supports a superset of the operations supported by the `NOCOPY` algorithm.

See InnoDB Online DDL Operations with ALGORITHM=INPLACE for more information.

NOCOPY Algorithm

The `NOCOPY` algorithm is supported. The `INPLACE` algorithm can sometimes be surprisingly slow in instances where it has to rebuild the clustered index, because when the clustered index has to be rebuilt, the whole table has to be rebuilt. The `NOCOPY` algorithm was introduced as a way to avoid this.

If an ALTER TABLE operation supports the `NOCOPY` algorithm, then it can be performed without rebuilding the clustered index.

If the `NOCOPY` algorithm is specified with the ALGORITHM clause or with the alter_algorithm system variable and if the ALTER TABLE operation does not support the `NOCOPY` algorithm, then an error are raised:

```
SET SESSION alter_algorithm='NOCOPY';

ALTER TABLE tab MODIFY COLUMN c INT;
ERROR 1846 (0A000): ALGORITHM=NOCOPY is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

In this case, raising an error is preferable, if the alternative is for the operation to rebuild the clustered index, and perform unexpectedly slowly.

Operations Supported by InnoDB with the `NOCOPY` Algorithm

With respect to the allowed operations, the `NOCOPY` algorithm supports a subset of the operations supported by the `INPLACE` algorithm, and it supports a superset of the operations supported by the `INSTANT` algorithm.

See InnoDB Online DDL Operations with ALGORITHM=NOCOPY for more information.

INSTANT Algorithm

The `INSTANT` algorithm is supported. The `INPLACE` algorithm can sometimes be surprisingly slow in instances where it has to modify data files. The `INSTANT` algorithm was introduced as a way to avoid this.

If an ALTER TABLE operation supports the `INSTANT` algorithm, then it can be performed without modifying any data files.

If the `INSTANT` algorithm is specified with the ALGORITHM clause or with the alter_algorithm system variable and if the ALTER TABLE operation does not support the `INSTANT` algorithm, then an error are raised:

```
SET SESSION alter_algorithm='INSTANT';

ALTER TABLE tab MODIFY COLUMN c INT;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

In this case, raising an error is preferable, if the alternative is for the operation to modify data files, and perform unexpectedly slowly.

Operations Supported by InnoDB with the INSTANT Algorithm

With respect to the allowed operations, the `INSTANT` algorithm supports a subset of the operations supported by the `NOCOPY` algorithm.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT for more information.

Alter Locking Strategies

InnoDB supports multiple locking strategies for performing DDL operations. This offers a significant performance improvement over previous versions. The supported locking strategies are:

- `DEFAULT` - This implies the default behavior for the specific operation.
- `NONE`
- `SHARED`
- `EXCLUSIVE`

Regardless of which locking strategy is used to perform a DDL operation, InnoDB will have to exclusively lock the table for a short time at the start and end of the operation's execution. This means that any active transactions that may have accessed the table must be committed or aborted for the operation to continue. This applies to most DDL statements, such as ALTER TABLE, CREATE INDEX, DROP INDEX, OPTIMIZE TABLE, RENAME TABLE, etc.

Specifying an Alter Locking Strategy

Specifying an Alter Locking Strategy Using the `LOCK` Clause

The ALTER TABLE statement supports the LOCK clause.

The LOCK clause can be used to specify the locking strategy that the user is willing to accept. It is supported by the ALTER TABLE and CREATE INDEX statements.

For example, if a user wanted to add a column to a table, but only if the operation is non-locking, then they could execute the following:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

ALTER TABLE tab ADD COLUMN c VARCHAR(50), ALGORITHM=INPLACE, LOCK=NONE;
```

If the LOCK clause is not explicitly set, then the operation uses `LOCK=DEFAULT`.

Specifying an Alter Locking Strategy Using `ALTER ONLINE TABLE`

ALTER ONLINE TABLE is equivalent to `LOCK=NONE`. Therefore, the ALTER ONLINE TABLE statement can be used to ensure that your ALTER TABLE operation allows all concurrent DML.

Supported Alter Locking Strategies

The supported algorithms are described in more details below.

To see which locking strategies InnoDB supports for each operation, see the pages that describe which operations are supported for each algorithm:

- InnoDB Online DDL Operations with ALGORITHM=INPLACE
- InnoDB Online DDL Operations with ALGORITHM=NOCOPY
- InnoDB Online DDL Operations with ALGORITHM=INSTANT

DEFAULT Locking Strategy

The default behavior, which occurs if `LOCK=DEFAULT` is specified, or if `LOCK` is not specified at all, acquire the least restrictive lock on the table that is supported for the specific operation. This permits the maximum amount of concurrency that is supported for the specific operation.

NONE Locking Strategy

The `NONE` locking strategy performs the operation without acquiring any lock on the table. This permits **all** concurrent DML.

If this locking strategy is not permitted for an operation, then an error is raised.

SHARED Locking Strategy

The `SHARED` locking strategy performs the operation after acquiring a read lock on the table. This permit **read-only** concurrent DML.

If this locking strategy is not permitted for an operation, then an error is raised.

EXCLUSIVE Locking Strategy

The `EXCLUSIVE` locking strategy performs the operation after acquiring a write lock on the table. This does **not** permit concurrent DML.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Online DDL Operations with the INPLACE Alter Algorithm

Supported Operations by Inheritance

When the ALGORITHM clause is set to `INPLACE`, the supported operations are a superset of the operations that are supported when the ALGORITHM clause is set to `NOCOPY`. Similarly, when the ALGORITHM clause is set to `NOCOPY`, the supported operations are a superset of the operations that are supported when the ALGORITHM clause is set to `INSTANT`.

Therefore, when the ALGORITHM clause is set to `INPLACE`, some operations are supported by inheritance. See the following additional pages for more information about these supported operations:

- InnoDB Online DDL Operations with ALGORITHM=NOCOPY
- InnoDB Online DDL Operations with ALGORITHM=INSTANT

Column Operations

`ALTER TABLE ... ADD COLUMN`

InnoDB supports adding columns to a table with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

With the exception of adding an auto-increment column, this operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD COLUMN c VARCHAR(50);
Query OK, 0 rows affected (0.006 sec)
```

This applies to ALTER TABLE … ADD COLUMN for InnoDB tables.

`ALTER TABLE ... DROP COLUMN`

InnoDB supports dropping columns from a table with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab DROP COLUMN c;
Query OK, 0 rows affected (0.021 sec)
```

This applies to ALTER TABLE … DROP COLUMN for InnoDB tables.

`ALTER TABLE ... MODIFY COLUMN`

This applies to ALTER TABLE … MODIFY COLUMN for InnoDB tables.

Reordering Columns

InnoDB supports reordering columns within a table with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) AFTER a;
Query OK, 0 rows affected (0.022 sec)
```

Changing the Data Type of a Column

InnoDB does **not** support modifying a column's data type with ALGORITHM set to `INPLACE` in most cases. There are some exceptions:

- In MariaDB 10.2.2 and later, InnoDB supports increasing the length of `VARCHAR` columns with ALGORITHM set to `INPLACE`, unless it would require changing the number of bytes requires to represent the column's length. A `VARCHAR` column that is between 0 and 255 bytes in size requires 1 byte to represent its length, while a `VARCHAR` column that is 256 bytes or longer requires 2 bytes to represent its length. This means that the length of a column cannot be increased with ALGORITHM set to `INPLACE` if the original length was less than 256 bytes, and the new length is 256 bytes or more.
- In MariaDB 10.4.3 and later, InnoDB supports increasing the length of `VARCHAR` columns with ALGORITHM set to `INPLACE` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Changing the Data Type of a Column for more information.

For example, this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c INT;
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

But this succeeds in MariaDB 10.2.2 and later, because the original length of the column is less than 256 bytes, and the new length is still less than 256 bytes:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) CHARACTER SET=latin1;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(100);
Query OK, 0 rows affected (0.005 sec)
```

But this fails in MariaDB 10.2.2 and later, because the original length of the column is less than 256 bytes, and the new length is greater than 256 bytes:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(255)
) CHARACTER SET=latin1;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(256);
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

Changing a Column to NULL

InnoDB supports modifying a column to allow NULL values with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50) NOT NULL
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) NULL;
Query OK, 0 rows affected (0.021 sec)
```

Changing a Column to NOT NULL

InnoDB supports modifying a column to **not** allow NULL values with ALGORITHM set to `INPLACE`. It is required for strict mode to be enabled in SQL_MODE. The operation will fail if the column contains any `NULL` values. Changes that would interfere with referential integrity are also not permitted.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) NOT NULL;
Query OK, 0 rows affected (0.021 sec)
```

Adding a New `ENUM` Option

InnoDB supports adding a new ENUM option to a column with ALGORITHM set to `INPLACE`. In order to add a new ENUM option with ALGORITHM set to `INPLACE`, the following requirements must be met:

- It must be added to the end of the list.
- The storage requirements must not change.

This operation only changes the table's metadata, so the table does not have to be rebuilt..

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c ENUM('red', 'green')
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c ENUM('red', 'green', 'blue');
Query OK, 0 rows affected (0.004 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c ENUM('red', 'green')
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c ENUM('red', 'blue', 'green');
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

Adding a New `SET` Option

InnoDB supports adding a new SET option to a column with ALGORITHM set to `INPLACE`. In order to add a new SET option with ALGORITHM set to `INPLACE`, the following requirements must be met:

- It must be added to the end of the list.
- The storage requirements must not change.

This operation only changes the table's metadata, so the table does not have to be rebuilt..

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c SET('red', 'green')
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c SET('red', 'green', 'blue');
Query OK, 0 rows affected (0.004 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c SET('red', 'green')
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c SET('red', 'blue', 'green');
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

Removing System Versioning from a Column

In MariaDB 10.3.8 and later, InnoDB supports removing system versioning from a column with ALGORITHM set to `INPLACE`. In order for this to work, the system_versioning_alter_history system variable must be set to `KEEP`. See MDEV-16330 for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50) WITH SYSTEM VERSIONING
);

SET SESSION system_versioning_alter_history='KEEP';
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) WITHOUT SYSTEM VERSIONING;
Query OK, 0 rows affected (0.005 sec)
```

`ALTER TABLE ... ALTER COLUMN`

This applies to ALTER TABLE … ALTER COLUMN for InnoDB tables.

Setting a Column's Default Value

InnoDB supports modifying a column's DEFAULT value with ALGORITHM set to `INPLACE`.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.
For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ALTER COLUMN c SET DEFAULT 'NO value explicitly provided.';
Query OK, 0 rows affected (0.005 sec)
```

Removing a Column's Default Value

InnoDB supports removing a column's DEFAULT value with ALGORITHM set to `INPLACE`.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50) DEFAULT 'NO value explicitly provided.'
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ALTER COLUMN c DROP DEFAULT;
Query OK, 0 rows affected (0.005 sec)
```

`ALTER TABLE ... CHANGE COLUMN`

InnoDB supports renaming a column with ALGORITHM set to `INPLACE`, unless the column's data type or attributes changed in addition to the name.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab CHANGE COLUMN c str VARCHAR(50);
Query OK, 0 rows affected (0.006 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab CHANGE COLUMN c num INT;
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

This applies to ALTER TABLE … CHANGE COLUMN for InnoDB tables.

Index Operations

`ALTER TABLE ... ADD PRIMARY KEY`

InnoDB supports adding a primary key to a table with ALGORITHM set to `INPLACE`.

If the new primary key column is not defined as NOT NULL, then it is highly recommended for strict mode to be enabled in SQL_MODE. Otherwise, `NULL` values are silently converted to the default value for the given data type, which is probably not the desired behavior in this scenario.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION sql_mode='STRICT_TRANS_TABLES';
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD PRIMARY KEY (a);
Query OK, 0 rows affected (0.021 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT,
   b VARCHAR(50),
   c VARCHAR(50)
);

INSERT INTO tab VALUES (NULL, NULL, NULL);

SET SESSION sql_mode='STRICT_TRANS_TABLES';
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD PRIMARY KEY (a);
ERROR 1265 (01000): Data truncated for column 'a' at row 1
```

And this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT,
   b VARCHAR(50),
   c VARCHAR(50)
);

INSERT INTO tab VALUES (1, NULL, NULL);
INSERT INTO tab VALUES (1, NULL, NULL);

SET SESSION sql_mode='STRICT_TRANS_TABLES';
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD PRIMARY KEY (a);
ERROR 1062 (23000): Duplicate entry '1' for key 'PRIMARY'
```

This applies to ALTER TABLE … ADD PRIMARY KEY for InnoDB tables.

`ALTER TABLE ... DROP PRIMARY KEY`

InnoDB does **not** support dropping a primary key with ALGORITHM set to `INPLACE` in most cases.

If you try to do so, then you will see an error. InnoDB only supports this operation with ALGORITHM set to `COPY`. Concurrent DML is *not* permitted.

However, there is an exception. If you are dropping a primary key, and adding a new one at the same time, then that operation can be performed with ALGORITHM set to `INPLACE`. This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab DROP PRIMARY KEY;
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Dropping a primary key is not allowed
without also adding a new primary key. Try ALGORITHM=COPY
```

But this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION sql_mode='STRICT_TRANS_TABLES';
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab DROP PRIMARY KEY, ADD PRIMARY KEY (b);
Query OK, 0 rows affected (0.020 sec)
```

This applies to ALTER TABLE … DROP PRIMARY KEY for InnoDB tables.

`ALTER TABLE ... ADD INDEX` and `CREATE INDEX`

This applies to ALTER TABLE … ADD INDEX and CREATE INDEX for InnoDB tables.

Adding a Plain Index

InnoDB supports adding a plain index to a table with ALGORITHM set to `INPLACE`. The table is not rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD INDEX b_index (b);
Query OK, 0 rows affected (0.010 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
CREATE INDEX b_index ON tab (b);
Query OK, 0 rows affected (0.011 sec)
```

Adding a Fulltext Index

InnoDB supports adding a FULLTEXT index to a table with ALGORITHM set to `INPLACE`. The table is not rebuilt in some cases.

However, there are some limitations, such as:

- Adding a FULLTEXT index to a table that does not have a user-defined `FTS_DOC_ID` column will require the table to be rebuilt once. When the table is rebuilt, the system adds a hidden `FTS_DOC_ID` column. From that point forward, adding additional FULLTEXT indexes to the same table will not require the table to be rebuilt when ALGORITHM is set to `INPLACE`.
- Only one FULLTEXT index may be added at a time when ALGORITHM is set to `INPLACE`.
- If a table has more than one FULLTEXT index, then it cannot be rebuilt by any ALTER TABLE operations when ALGORITHM is set to `INPLACE`.
- If a table has a FULLTEXT index, then it cannot be rebuilt by any ALTER TABLE operations when the LOCK clause is set to `NONE`.

This operation supports a read-only locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `SHARED`. When this strategy is used, read-only concurrent DML is permitted.

For example, this succeeds, but requires the table to be rebuilt, so that the hidden `FTS_DOC_ID` column can be added:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.055 sec)
```

And this succeeds in the same way as above:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
CREATE FULLTEXT INDEX b_index ON tab (b);
Query OK, 0 rows affected (0.041 sec)
```

And this succeeds, and the second command does not require the table to be rebuilt:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.043 sec)

ALTER TABLE tab ADD FULLTEXT INDEX c_index (c);
Query OK, 0 rows affected (0.017 sec)
```

But this second command fails, because only one FULLTEXT index can be added at a time:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.041 sec)

ALTER TABLE tab ADD FULLTEXT INDEX c_index (c), ADD FULLTEXT INDEX d_index (d);
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: InnoDB presently supports one FULLTEXT
index creation at a time. Try ALGORITHM=COPY
```

And this third command fails, because a table cannot be rebuilt when it has more than one FULLTEXT index:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.040 sec)

ALTER TABLE tab ADD FULLTEXT INDEX c_index (c);
Query OK, 0 rows affected (0.015 sec)

ALTER TABLE tab FORCE;
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: InnoDB presently supports one FULLTEXT
index creation at a time. Try ALGORITHM=COPY
```

Adding a Spatial Index

InnoDB supports adding a SPATIAL index to a table with ALGORITHM set to `INPLACE`.

However, there are some limitations, such as:

- If a table has a SPATIAL index, then it cannot be rebuilt by any ALTER TABLE operations when the LOCK clause is set to `NONE`.

This operation supports a read-only locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `SHARED`. When this strategy is used, read-only concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c GEOMETRY NOT NULL
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD SPATIAL INDEX c_index (c);
Query OK, 0 rows affected (0.006 sec)
```

And this succeeds in the same way as above:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c GEOMETRY NOT NULL
);

SET SESSION alter_algorithm='INPLACE';
CREATE SPATIAL INDEX c_index ON tab (c);
Query OK, 0 rows affected (0.006 sec)
```

`ALTER TABLE ... DROP INDEX` and `DROP INDEX`

InnoDB supports dropping indexes from a table with ALGORITHM set to `INPLACE`.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   INDEX b_index (b)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab DROP INDEX b_index;
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   INDEX b_index (b)
);

SET SESSION alter_algorithm='INPLACE';
DROP INDEX b_index ON tab;
```

This applies to ALTER TABLE … DROP INDEX and DROP INDEX for InnoDB tables.

`ALTER TABLE ... ADD FOREIGN KEY`

InnoDB supports adding foreign key constraints to a table with ALGORITHM set to `INPLACE`. In order to add a new foreign key constraint to a table with ALGORITHM set to `INPLACE`, the foreign_key_checks system variable needs to be set to `OFF`. If it is set to `ON`, then `ALGORITHM=COPY` is required.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this fails:

```
CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT
);

CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab1 ADD FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a);
ERROR 1846 (0A000): ALGORITHM=INPLACE is not supported. Reason: Adding foreign keys needs
foreign_key_checks=OFF. Try ALGORITHM=COPY
```

But this succeeds:

```
CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT
);

CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION foreign_key_checks=OFF;
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab1 ADD FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a);
Query OK, 0 rows affected (0.011 sec)
```

This applies to ALTER TABLE … ADD FOREIGN KEY for InnoDB tables.

`ALTER TABLE ... DROP FOREIGN KEY`

InnoDB supports dropping foreign key constraints from a table with ALGORITHM set to `INPLACE`.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT,
   FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab1 DROP FOREIGN KEY tab2_fk;
Query OK, 0 rows affected (0.005 sec)
```

This applies to ALTER TABLE … DROP FOREIGN KEY for InnoDB tables.

Table Operations

`ALTER TABLE ... AUTO_INCREMENT=...`

InnoDB supports changing a table's AUTO_INCREMENT value with ALGORITHM set to `INPLACE`. This operation should finish instantly. The table is not rebuilt.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab AUTO_INCREMENT=100;
Query OK, 0 rows affected (0.004 sec)
```

This applies to ALTER TABLE … AUTO_INCREMENT=… for InnoDB tables.

`ALTER TABLE ... ROW_FORMAT=...`

InnoDB supports changing a table's row format with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=DYNAMIC;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ROW_FORMAT=COMPRESSED;
Query OK, 0 rows affected (0.025 sec)
```

This applies to ALTER TABLE … ROW_FORMAT=… for InnoDB tables.

`ALTER TABLE ... KEY_BLOCK_SIZE=...`

InnoDB supports changing a table's KEY_BLOCK_SIZE with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=COMPRESSED
  KEY_BLOCK_SIZE=4;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab KEY_BLOCK_SIZE=2;
Query OK, 0 rows affected (0.021 sec)
```

This applies to KEY_BLOCK_SIZE=... for InnoDB tables.

`ALTER TABLE ... PAGE_COMPRESSED=...` and `ALTER TABLE ... PAGE_COMPRESSION_LEVEL=...`

In MariaDB 10.3.10 and later, InnoDB supports setting a table's PAGE_COMPRESSED value to `1` with ALGORITHM set to `INPLACE`. InnoDB also supports changing a table's PAGE_COMPRESSED value from `1` to `0` with ALGORITHM set to `INPLACE`.

In these versions, InnoDB also supports changing a table's PAGE_COMPRESSION_LEVEL value with ALGORITHM set to `INPLACE`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

See MDEV-16328 for more information.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab PAGE_COMPRESSED=1;
Query OK, 0 rows affected (0.006 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) PAGE_COMPRESSED=1;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab PAGE_COMPRESSED=0;
Query OK, 0 rows affected (0.020 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) PAGE_COMPRESSED=1
  PAGE_COMPRESSION_LEVEL=5;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab PAGE_COMPRESSION_LEVEL=4;
Query OK, 0 rows affected (0.006 sec)
```

This applies to PAGE_COMPRESSED=… and PAGE_COMPRESSION_LEVEL=… for InnoDB tables.

`ALTER TABLE ... DROP SYSTEM VERSIONING`

InnoDB supports dropping system versioning from a table with ALGORITHM set to `INPLACE`.

This operation supports the read-only locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `SHARED`. When this strategy is used, read-only concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) WITH SYSTEM VERSIONING;

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab DROP SYSTEM VERSIONING;
```

This applies to ALTER TABLE … DROP SYSTEM VERSIONING for InnoDB tables.

`ALTER TABLE ... DROP CONSTRAINT`

In MariaDB 10.3.6 and later, InnoDB supports dropping a CHECK constraint from a table with ALGORITHM set to `INPLACE`. See MDEV-16331 for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   CONSTRAINT b_not_empty CHECK (b != '')
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab DROP CONSTRAINT b_not_empty;
Query OK, 0 rows affected (0.004 sec)
```

This applies to ALTER TABLE … DROP CONSTRAINT for InnoDB tables.

`ALTER TABLE ... FORCE`

InnoDB supports forcing a table rebuild with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab FORCE;
Query OK, 0 rows affected (0.022 sec)
```

This applies to ALTER TABLE … FORCE for InnoDB tables.

`ALTER TABLE ... ENGINE=InnoDB`

InnoDB supports forcing a table rebuild with ALGORITHM set to `INPLACE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ENGINE=InnoDB;
Query OK, 0 rows affected (0.022 sec)
```

This applies to ALTER TABLE … ENGINE=InnoDB for InnoDB tables.

`OPTIMIZE TABLE ...`

InnoDB supports optimizing a table with ALGORITHM set to `INPLACE`.

If the innodb_defragment system variable is set to `OFF`, and if the innodb_optimize_fulltext_only system variable is also set to `OFF`, then `OPTIMIZE TABLE` are equivalent to `ALTER TABLE … FORCE`.

The table is rebuilt, which means that all of the data is reorganized substantially, and the indexes are rebuilt. As a result, the operation is quite expensive.

If either of the previously mentioned system variables is set to `ON`, then `OPTIMIZE TABLE` will optimize some data without rebuilding the table. However, the file size will not be reduced.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SHOW GLOBAL VARIABLES WHERE Variable_name IN('innodb_defragment', 'innodb_optimize_fulltext_only');
+--------------------------------+-------+
| Variable_name                  | Value |
+--------------------------------+-------+
| innodb_defragment              | OFF   |
| innodb_optimize_fulltext_only | OFF   |
+--------------------------------+-------+

SET SESSION alter_algorithm='INPLACE';
OPTIMIZE TABLE tab;
+---------+----------+----------+-------------------------------------------------------------------+
| Table   | Op       | Msg_type | Msg_text                                                          |
+---------+----------+----------+-------------------------------------------------------------------+
| db1.tab | optimize | note     | Table does not support optimize, doing recreate + analyze instead |
| db1.tab | optimize | status   | OK                                                                |
+---------+----------+----------+-------------------------------------------------------------------+
2 rows in set (0.026 sec)
```

And this succeeds, but the table is not rebuilt:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET GLOBAL innodb_defragment=ON;
SHOW GLOBAL VARIABLES WHERE Variable_name IN('innodb_defragment', 'innodb_optimize_fulltext_only');
+--------------------------------+-------+
| Variable_name                  | Value |
+--------------------------------+-------+
| innodb_defragment              | ON    |
| innodb_optimize_fulltext_only | OFF   |
+--------------------------------+-------+

SET SESSION alter_algorithm='INPLACE';
OPTIMIZE TABLE tab;
+---------+----------+----------+----------+
| Table   | Op       | Msg_type | Msg_text |
+---------+----------+----------+----------+
| db1.tab | optimize | status   | OK       |
+---------+----------+----------+----------+
1 row in set (0.004 sec)
```

This applies to OPTIMIZE TABLE for InnoDB tables.

`ALTER TABLE ... RENAME TO` and `RENAME TABLE ...`

InnoDB supports renaming a table with ALGORITHM set to `INPLACE`.

This operation only changes the table's metadata, so the table does not have to be rebuilt.

This operation supports the exclusive locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `EXCLUSIVE`. When this strategy is used, concurrent DML is **not** permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab RENAME TO old_tab;
Query OK, 0 rows affected (0.011 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
RENAME TABLE tab TO old_tab;
```

This applies to ALTER TABLE … RENAME TO and RENAME TABLE for InnoDB tables.

Limitations

Limitations Related to Fulltext Indexes

- If a table has more than one FULLTEXT index, then it cannot be rebuilt by any ALTER TABLE operations when ALGORITHM is set to `INPLACE`.
- If a table has a FULLTEXT index, then it cannot be rebuilt by any ALTER TABLE operations when the LOCK clause is set to `NONE`.

Limitations Related to Spatial Indexes

- If a table has a SPATIAL index, then it cannot be rebuilt by any ALTER TABLE operations when the LOCK clause is set to `NONE`.

Limitations Related to Generated (Virtual and Persistent/Stored) Columns

Generated columns do not currently support online DDL for all of the same operations that are supported for “real” columns.

See Generated (Virtual and Persistent/Stored) Columns: Statement Support for more information on the limitations.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Online DDL Operations with the INSTANT Alter Algorithm

Column Operations

`ALTER TABLE ... ADD COLUMN`

In MariaDB 10.3.2 and later, InnoDB supports adding columns to a table with ALGORITHM set to `INSTANT` if the new column is the last column in the table. See MDEV-11369 for more information. If the table has a hidden `FTS_DOC_ID` column is present, then this is not supported.

In MariaDB 10.4 and later, InnoDB supports adding columns to a table with ALGORITHM set to `INSTANT`, regardless of where in the column list the new column is added.

When this operation is performed with ALGORITHM set to `INSTANT`, the tablespace file will have a non-canonical storage format. See Non-canonical Storage Format Caused by Some Operations for more information.

With the exception of adding an auto-increment column, this operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ADD COLUMN c VARCHAR(50);
Query OK, 0 rows affected (0.004 sec)
```

And this succeeds in MariaDB 10.4 and later:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ADD COLUMN c VARCHAR(50) AFTER a;
Query OK, 0 rows affected (0.004 sec)
```

This applies to ALTER TABLE … ADD COLUMN for InnoDB tables.

See Instant ADD COLUMN for InnoDB for more information.

`ALTER TABLE ... DROP COLUMN`

In MariaDB 10.4 and later, InnoDB supports dropping columns from a table with ALGORITHM set to `INSTANT`. See MDEV-15562 for more information.

When this operation is performed with ALGORITHM set to `INSTANT`, the tablespace file will have a non-canonical storage format. See Non-canonical Storage Format Caused by Some Operations for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab DROP COLUMN c;
Query OK, 0 rows affected (0.004 sec)
```

This applies to ALTER TABLE … DROP COLUMN for InnoDB tables.

`ALTER TABLE ... MODIFY COLUMN`

This applies to ALTER TABLE … MODIFY COLUMN for InnoDB tables.

Reordering Columns

In MariaDB 10.4 and later, InnoDB supports reordering columns within a table with ALGORITHM set to `INSTANT`. See MDEV-15562 for more information.

When this operation is performed with ALGORITHM set to `INSTANT`, the tablespace file will have a non-canonical storage format. See Non-canonical Storage Format Caused by Some Operations for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) AFTER a;
Query OK, 0 rows affected (0.004 sec)
```

Changing the Data Type of a Column

InnoDB does **not** support modifying a column's data type with ALGORITHM set to `INSTANT` in most cases. There are some exceptions:

- InnoDB supports increasing the length of `VARCHAR` columns with ALGORITHM set to `INSTANT`, unless it would require changing the number of bytes requires to represent the column's length. A `VARCHAR` column that is between 0 and 255 bytes in size requires 1 byte to represent its length, while a `VARCHAR` column that is 256 bytes or longer requires 2 bytes to represent its length. This means that the length of a column cannot be increased with ALGORITHM set to `INSTANT` if the original length was less than 256 bytes, and the new length is 256 bytes or more.
- In MariaDB 10.4.3 and later, InnoDB supports increasing the length of `VARCHAR` columns with ALGORITHM set to `INSTANT` with no restrictions if the ROW_FORMAT table option is set to REDUNDANT. See MDEV-15563 for more information.
- In MariaDB 10.4.3 and later, InnoDB also supports increasing the length of `VARCHAR` columns with ALGORITHM set to `INSTANT` in a more limited manner if the ROW_FORMAT table option is set to COMPACT, DYNAMIC, or COMPRESSED. In this scenario, the following limitations apply:
  - The length can be increased with ALGORITHM set to `INSTANT` if the original length of the column is 127 bytes or less, and the new length of the column is 256 bytes or more.
  - The length can be increased with ALGORITHM set to `INSTANT` if the original length of the column is 255 bytes or less, and the new length of the column is still 255 bytes or less.
  - The length can be increased with ALGORITHM set to `INSTANT` if the original length of the column is 256 bytes or more, and the new length of the column is still 256 bytes or more.
  - The length can not be increased with ALGORITHM set to `INSTANT` if the original length was between 128 bytes and 255 bytes, and the new length is 256 bytes or more.
  - See MDEV-15563 for more information.

The supported operations in this category support the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c INT;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

But this succeeds because the original length of the column is less than 256 bytes, and the new length is still less than 256 bytes:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) CHARACTER SET=latin1;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(100);
Query OK, 0 rows affected (0.005 sec)
```

But this fails because the original length of the column is between 128 bytes and 255 bytes, and the new length is greater than 256 bytes:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(255)
) CHARACTER SET=latin1;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(256);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

But this succeeds in MariaDB 10.4.3 and later because the table has `ROW_FORMAT=REDUNDANT`:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(200)
) ROW_FORMAT=REDUNDANT;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(300);
Query OK, 0 rows affected (0.004 sec)
```

And this succeeds in MariaDB 10.4.3 and later because the table has `ROW_FORMAT=DYNAMIC` and the column's original length is 127 bytes or less:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(127)
) ROW_FORMAT=DYNAMIC
  CHARACTER SET=latin1;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(300);
Query OK, 0 rows affected (0.003 sec)
```

And this succeeds in MariaDB 10.4.3 and later because the table has `ROW_FORMAT=COMPRESSED` and the column's original length is 127 bytes or less:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(127)
) ROW_FORMAT=COMPRESSED
  CHARACTER SET=latin1;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(300);
Query OK, 0 rows affected (0.003 sec)
```

But this fails even in MariaDB 10.4.3 and later because the table has `ROW_FORMAT=DYNAMIC` and the column's original length is between 128 bytes and 255 bytes:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(128)
) ROW_FORMAT=DYNAMIC
  CHARACTER SET=latin1;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(300);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

Changing a Column to NULL

In MariaDB 10.4.3 and later, InnoDB supports modifying a column to allow NULL values with ALGORITHM set to `INSTANT` if the ROW_FORMAT table option is set to REDUNDANT. See MDEV-15563 for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50) NOT NULL
) ROW_FORMAT=REDUNDANT;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) NULL;
Query OK, 0 rows affected (0.004 sec)
```

Changing a Column to NOT NULL

InnoDB does **not** support modifying a column to **not** allow NULL values with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=REDUNDANT;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) NOT NULL;
ERROR 1845 (0A000): ALGORITHM=INSTANT is not supported for this operation. Try ALGORITHM=INPLACE
```

Adding a New `ENUM` Option

InnoDB supports adding a new ENUM option to a column with ALGORITHM set to `INSTANT`. In order to add a new ENUM option with ALGORITHM set to `INSTANT`, the following requirements must be met:

- It must be added to the end of the list.
- The storage requirements must not change.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c ENUM('red', 'green')
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c ENUM('red', 'green', 'blue');
Query OK, 0 rows affected (0.002 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c ENUM('red', 'green')
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c ENUM('red', 'blue', 'green');
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

Adding a New `SET` Option

InnoDB supports adding a new SET option to a column with ALGORITHM set to `INSTANT`. In order to add a new SET option with ALGORITHM set to `INSTANT`, the following requirements must be met:

- It must be added to the end of the list.
- The storage requirements must not change.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c SET('red', 'green')
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c SET('red', 'green', 'blue');
Query OK, 0 rows affected (0.002 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c SET('red', 'green')
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c SET('red', 'blue', 'green');
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

Removing System Versioning from a Column

In MariaDB 10.3.8 and later, InnoDB supports removing system versioning from a column with ALGORITHM set to `INSTANT`. In order for this to work, the system_versioning_alter_history system variable must be set to `KEEP`. See MDEV-16330 for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50) WITH SYSTEM VERSIONING
);

SET SESSION system_versioning_alter_history='KEEP';
SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) WITHOUT SYSTEM VERSIONING;
Query OK, 0 rows affected (0.004 sec)
```

`ALTER TABLE ... ALTER COLUMN`

This applies to ALTER TABLE … ALTER COLUMN for InnoDB tables.

Setting a Column's Default Value

InnoDB supports modifying a column's DEFAULT value with ALGORITHM set to `INSTANT`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ALTER COLUMN c SET DEFAULT 'NO value explicitly provided.';
Query OK, 0 rows affected (0.003 sec)
```

Removing a Column's Default Value

InnoDB supports removing a column's DEFAULT value with ALGORITHM set to `INSTANT`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50) DEFAULT 'NO value explicitly provided.'
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ALTER COLUMN c DROP DEFAULT;
Query OK, 0 rows affected (0.002 sec)
```

`ALTER TABLE ... CHANGE COLUMN`

InnoDB supports renaming a column with ALGORITHM set to `INSTANT`, unless the column's data type or attributes changed in addition to the name.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab CHANGE COLUMN c str VARCHAR(50);
Query OK, 0 rows affected (0.004 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab CHANGE COLUMN c num INT;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Cannot change column type INPLACE. Try
ALGORITHM=COPY
```

This applies to ALTER TABLE … CHANGE COLUMN for InnoDB tables.

Index Operations

`ALTER TABLE ... ADD PRIMARY KEY`

InnoDB does **not** support adding a primary key to a table with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION sql_mode='STRICT_TRANS_TABLES';
SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ADD PRIMARY KEY (a);
ERROR 1845 (0A000): ALGORITHM=INSTANT is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … ADD PRIMARY KEY for InnoDB tables.

`ALTER TABLE ... DROP PRIMARY KEY`

InnoDB does **not** support dropping a primary key with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab DROP PRIMARY KEY;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Dropping a primary key is not allowed
without also adding a new primary key. Try ALGORITHM=COPY
```

This applies to ALTER TABLE … DROP PRIMARY KEY for InnoDB tables.

`ALTER TABLE ... ADD INDEX` and `CREATE INDEX`

This applies to ALTER TABLE … ADD INDEX and CREATE INDEX for InnoDB tables.

Adding a Plain Index

InnoDB does **not** support adding a plain index to a table with ALGORITHM set to `INSTANT`.

For example, this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ADD INDEX b_index (b);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

And this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
CREATE INDEX b_index ON tab (b);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

Adding a Fulltext Index

InnoDB does **not** support adding a FULLTEXT index to a table with ALGORITHM set to `INSTANT`.

For example, this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.042 sec)

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ADD FULLTEXT INDEX c_index (c);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

And this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
CREATE FULLTEXT INDEX b_index ON tab (b);
Query OK, 0 rows affected (0.040 sec)

SET SESSION alter_algorithm='INSTANT';
CREATE FULLTEXT INDEX c_index ON tab (c);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

Adding a Spatial Index

InnoDB does **not** support adding a SPATIAL index to a table with ALGORITHM set to `INSTANT`.

For example, this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c GEOMETRY NOT NULL
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ADD SPATIAL INDEX c_index (c);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

And this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c GEOMETRY NOT NULL
);

SET SESSION alter_algorithm='INSTANT';
CREATE SPATIAL INDEX c_index ON tab (c);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

`ALTER TABLE ... ADD FOREIGN KEY`

InnoDB does **not** support adding foreign key constraints to a table with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT
);

CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION foreign_key_checks=OFF;
SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab1 ADD FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a);
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: ADD INDEX. Try ALGORITHM=NOCOPY
```

This applies to ALTER TABLE … ADD FOREIGN KEY for InnoDB tables.

`ALTER TABLE ... DROP FOREIGN KEY`

InnoDB supports dropping foreign key constraints from a table with ALGORITHM set to `INSTANT`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT,
   FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab1 DROP FOREIGN KEY tab2_fk;
Query OK, 0 rows affected (0.004 sec)
```

This applies to ALTER TABLE … DROP FOREIGN KEY for InnoDB tables.

Table Operations

`ALTER TABLE ... AUTO_INCREMENT=...`

InnoDB supports changing a table's AUTO_INCREMENT value with ALGORITHM set to `INSTANT`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab AUTO_INCREMENT=100;
Query OK, 0 rows affected (0.002 sec)
```

This applies to ALTER TABLE … AUTO_INCREMENT=… for InnoDB tables.

`ALTER TABLE ... ROW_FORMAT=...`

InnoDB does **not** support changing a table's row format with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=DYNAMIC;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ROW_FORMAT=COMPRESSED;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Changing table options requires the table
to be rebuilt. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … ROW_FORMAT=… for InnoDB tables.

`ALTER TABLE ... KEY_BLOCK_SIZE=...`

InnoDB does **not** support changing a table's KEY_BLOCK_SIZE with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=COMPRESSED
  KEY_BLOCK_SIZE=4;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab KEY_BLOCK_SIZE=2;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Changing table options requires the table
to be rebuilt. Try ALGORITHM=INPLACE
```

This applies to KEY_BLOCK_SIZE=… for InnoDB tables.

`ALTER TABLE ... PAGE_COMPRESSED=1` and `ALTER TABLE ... PAGE_COMPRESSION_LEVEL=...`

In MariaDB 10.3.10 and later, InnoDB supports setting a table's PAGE_COMPRESSED value to `1` with ALGORITHM set to `INSTANT`. InnoDB does **not** support changing a table's PAGE_COMPRESSED value from `1` to `0` with ALGORITHM set to `INSTANT`.

In these versions, InnoDB also supports changing a table's PAGE_COMPRESSION_LEVEL value with ALGORITHM set to `INSTANT`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

See MDEV-16328 for more information.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab PAGE_COMPRESSED=1;
Query OK, 0 rows affected (0.004 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) PAGE_COMPRESSED=1
  PAGE_COMPRESSION_LEVEL=5;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab PAGE_COMPRESSION_LEVEL=4;
Query OK, 0 rows affected (0.004 sec)
```

But this fails:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) PAGE_COMPRESSED=1;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab PAGE_COMPRESSED=0;
ERROR 1846 (0A000): ALGORITHM=INSTANT is not supported. Reason: Changing table options requires the table
to be rebuilt. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … PAGE_COMPRESSED=… and ALTER TABLE … PAGE_COMPRESSION_LEVEL=… for InnoDB tables.

`ALTER TABLE ... DROP SYSTEM VERSIONING`

InnoDB does **not** support dropping system versioning from a table with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) WITH SYSTEM VERSIONING;

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab DROP SYSTEM VERSIONING;
ERROR 1845 (0A000): ALGORITHM=INSTANT is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … DROP SYSTEM VERSIONING for InnoDB tables.

`ALTER TABLE ... DROP CONSTRAINT`

In MariaDB 10.3.6 and later, InnoDB supports dropping a CHECK constraint from a table with ALGORITHM set to `INSTANT`. See MDEV-16331 for more information.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   CONSTRAINT b_not_empty CHECK (b != '')
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab DROP CONSTRAINT b_not_empty;
Query OK, 0 rows affected (0.002 sec)
```

This applies to ALTER TABLE … DROP CONSTRAINT for InnoDB tables.

`ALTER TABLE ... FORCE`

InnoDB does **not** support forcing a table rebuild with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab FORCE;
ERROR 1845 (0A000): ALGORITHM=INSTANT is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … FORCE for InnoDB tables.

`ALTER TABLE ... ENGINE=InnoDB`

InnoDB does **not** support forcing a table rebuild with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab ENGINE=InnoDB;
ERROR 1845 (0A000): ALGORITHM=INSTANT is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … ENGINE=InnoDB for InnoDB tables.

`OPTIMIZE TABLE ...`

InnoDB does **not** support optimizing a table with ALGORITHM set to `INSTANT`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SHOW GLOBAL VARIABLES WHERE Variable_name IN('innodb_defragment', 'innodb_optimize_fulltext_only');
+-------------------------------+-------+
| Variable_name                 | Value |
+-------------------------------+-------+
| innodb_defragment             | OFF   |
| innodb_optimize_fulltext_only | OFF   |
+-------------------------------+-------+
2 rows in set (0.001 sec)

SET SESSION alter_algorithm='INSTANT';
OPTIMIZE TABLE tab;
+---------+----------+----------+-------------------------------------------------------------------------------
------+
| Table   | Op       | Msg_type | Msg_text
|
+---------+----------+----------+-------------------------------------------------------------------------------
------+
| db1.tab | optimize | note     | Table does not support optimize, doing recreate + analyze instead
|
| db1.tab | optimize | error    | ALGORITHM=INSTANT is not supported for this operation. Try
ALGORITHM=INPLACE |
| db1.tab | optimize | status   | Operation failed
|
+---------+----------+----------+-------------------------------------------------------------------------------
------+
3 rows in set, 1 warning (0.002 sec)
```

This applies to OPTIMIZE TABLE for InnoDB tables.

`ALTER TABLE ... RENAME TO` and `RENAME TABLE ...`

InnoDB supports renaming a table with ALGORITHM set to `INSTANT`.

This operation supports the exclusive locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `EXCLUSIVE`. When this strategy is used, concurrent DML is **not** permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
ALTER TABLE tab RENAME TO old_tab;
Query OK, 0 rows affected (0.008 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INSTANT';
RENAME TABLE tab TO old_tab;
Query OK, 0 rows affected (0.008 sec)
```

This applies to ALTER TABLE … RENAME TO and RENAME TABLE for InnoDB tables.

Limitations

Limitations Related to Generated (Virtual and Persistent/Stored) Columns

Generated columns do not currently support online DDL for all of the same operations that are supported for “real” columns.

See Generated (Virtual and Persistent/Stored) Columns: Statement Support for more information on the limitations.

Non-canonical Storage Format Caused by Some Operations

Some operations cause a table’s tablespace file to use a non-canonical storage format when the `INSTANT` algorithm is used. The affected operations include:

- Adding a column.
- Dropping a column.
- Reordering columns.

These operations require the following non-canonical changes to the storage format:

- A hidden metadata record at the start of the clustered index is used to store each column’s DEFAULT value. This makes it possible to add new columns that have default values without rebuilding the table.
- A BLOB in the hidden metadata record is used to store column mappings. This makes it possible to drop or reorder columns without rebuilding the table. This also makes it possible to add columns to any position or drop columns from any position in the table without rebuilding the table.
- If a column is dropped, old records will contain garbage in that column’s former position, and new records are written with NULL values, empty strings, or dummy values.

This non-canonical storage format has the potential to incur some performance or storage overhead for all subsequent DML operations. If you notice some issues like this and you want to normalize a table’s storage format to avoid this problem, then you can do so by forcing a table rebuild by executing ALTER TABLE … FORCE with ALGORITHM set to `INPLACE`:

```
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab FORCE;
Query OK, 0 rows affected (0.008 sec)
```

However, keep in mind that there are certain scenarios where you may not be able to rebuild the table with ALGORITHM set to `INPLACE`. See InnoDB Online DDL Operations with ALGORITHM=INPLACE: Limitations for more information on those cases. If you hit one of those scenarios, but you still want to rebuild the table, then you would have to do so with ALGORITHM set to `COPY`.

Known Bugs

There are some known bugs that could lead to issues when an InnoDB DDL operation is performed using the INSTANT algorithm. This algorithm will usually be chosen by default if the operation supports the algorithm.

The effect of many of these bugs is that the table seems to *forget* that its tablespace file is in the non-canonical storage format.

If you are concerned that a table may be affected by one of these bugs, then your best option would be to normalize the table structure. This can be done by rebuilding the table:

```
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab FORCE;
Query OK, 0 rows affected (0.008 sec)
```

If you are concerned about these bugs, and you want to perform an operation that supports the INSTANT algorithm, but you want to avoid using that algorithm, then you can set the algorithm to INPLACE and add the `FORCE` keyword to the ALTER TABLE statement:

```
SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD COLUMN c VARCHAR(50), FORCE;
```

Closed Bugs

- MDEV-20066: This bug could cause a table to become corrupt if a column was added instantly. It is fixed in MariaDB 10.3.18 and MariaDB 10.4.8.
- MDEV-20117: This bug could cause a table to become corrupt if a column was dropped instantly. It is fixed in MariaDB 10.4.9.
- MDEV-19743: This bug could cause a table to become corrupt during page reorganization if a column was added instantly. It is fixed in MariaDB 10.3.17 and MariaDB 10.4.7.
- MDEV-19783: This bug could cause a table to become corrupt if a column was added instantly. It is fixed in MariaDB 10.3.17 and MariaDB 10.4.7
- MDEV-20090: This bug could cause a table to become corrupt if columns were added, dropped, or reordered instantly. It is fixed in MariaDB 10.4.9.
- MDEV-18519: This bug could cause a table to become corrupt if a column was added instantly. It is fixed in MariaDB 10.6.9, MariaDB 10.7.5, MariaDB 10.8.4 and MariaDB 10.9.2.
- MDEV-18519: This bug could cause a table to become corrupt if a column was added instantly. This isn't and won't be fixed in versions less than MariaDB 10.6.

InnoDB Online DDL Operations with the NOCOPY Alter Algorithm

Supported Operations by Inheritance

When the ALGORITHM clause is set to `NOCOPY`, the supported operations are a superset of the operations that are supported when the ALGORITHM clause is set to `INSTANT`.

Therefore, when the ALGORITHM clause is set to `NOCOPY`, some operations are supported by inheritance. See the following additional pages for more information about these supported operations:

- InnoDB Online DDL Operations with ALGORITHM=INSTANT

Column Operations

`ALTER TABLE ... ADD COLUMN`

In MariaDB 10.3.2 and later, InnoDB supports adding columns to a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … ADD COLUMN for more information.

This applies to ALTER TABLE … ADD COLUMN for InnoDB tables.

`ALTER TABLE ... DROP COLUMN`

In MariaDB 10.4 and later, InnoDB supports dropping columns from a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … DROP COLUMN for more information.

This applies to ALTER TABLE … DROP COLUMN for InnoDB tables.

`ALTER TABLE ... MODIFY COLUMN`

This applies to ALTER TABLE … MODIFY COLUMN for InnoDB tables.

Reordering Columns

In MariaDB 10.4 and later, InnoDB supports reordering columns within a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Reordering Columns for more information.

Changing the Data Type of a Column

InnoDB does **not** support modifying a column's data type with ALGORITHM set to `NOCOPY` in most cases. There are a few exceptions in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Changing the Data Type of a Column for more information.

Changing a Column to NULL

In MariaDB 10.4.3 and later, InnoDB supports modifying a column to allow NULL values with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Changing a Column to NULL for more information.

Changing a Column to NOT NULL

InnoDB does **not** support modifying a column to **not** allow NULL values with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=REDUNDANT;

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab MODIFY COLUMN c VARCHAR(50) NOT NULL;
ERROR 1845 (0A000): ALGORITHM=NOCOPY is not supported for this operation. Try ALGORITHM=INPLACE
```

Adding a New `ENUM` Option

InnoDB supports adding a new ENUM option to a column with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Adding a New ENUM Option for more information.

Adding a New `SET` Option

InnoDB supports adding a new SET option to a column with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Adding a New SET Option for more information.

Removing System Versioning from a Column

In MariaDB 10.3.8 and later, InnoDB supports removing system versioning from a column with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Removing System Versioning from a Column for more information.

`ALTER TABLE ... ALTER COLUMN`

This applies to ALTER TABLE … ALTER COLUMN for InnoDB tables.

Setting a Column's Default Value

InnoDB supports modifying a column's DEFAULT value with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Setting a Column's Default Value for more information.

Removing a Column's Default Value

InnoDB supports removing a column's DEFAULT value with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Removing a Column's Default Value for more information.

`ALTER TABLE ... CHANGE COLUMN`

InnoDB supports renaming a column with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … CHANGE COLUMN for more information.

This applies to ALTER TABLE … CHANGE COLUMN for InnoDB tables.

Index Operations

`ALTER TABLE ... ADD PRIMARY KEY`

InnoDB does **not** support adding a primary key to a table with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION sql_mode='STRICT_TRANS_TABLES';
SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ADD PRIMARY KEY (a);
ERROR 1845 (0A000): ALGORITHM=NOCOPY is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … ADD PRIMARY KEY for InnoDB tables.

`ALTER TABLE ... DROP PRIMARY KEY`

InnoDB does **not** support dropping a primary key with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab DROP PRIMARY KEY;
ERROR 1846 (0A000): ALGORITHM=NOCOPY is not supported. Reason: Dropping a primary key is not allowed
without also adding a new primary key. Try ALGORITHM=COPY
```

This applies to ALTER TABLE … DROP PRIMARY KEY for InnoDB tables.

`ALTER TABLE ... ADD INDEX` and `CREATE INDEX`

This applies to ALTER TABLE … ADD INDEX and CREATE INDEX for InnoDB tables.

Adding a Plain Index

InnoDB supports adding a plain index to a table with ALGORITHM set to `NOCOPY`.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ADD INDEX b_index (b);
Query OK, 0 rows affected (0.009 sec)
```

And this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='NOCOPY';
CREATE INDEX b_index ON tab (b);
Query OK, 0 rows affected (0.009 sec)
```

Adding a Fulltext Index

InnoDB supports adding a FULLTEXT index to a table with ALGORITHM set to `NOCOPY`.

However, there are some limitations, such as:

- Adding a FULLTEXT index to a table that does not have a user-defined `FTS_DOC_ID` column will require the table to be rebuilt once. When the table is rebuilt, the system adds a hidden `FTS_DOC_ID` column. This initial operation will have to be performed with ALGORITHM set to `INPLACE`.From that point forward, adding additional FULLTEXT indexes to the same table will not require the table to be rebuilt, and ALGORITHM can be set to `NOCOPY`.
- Only one FULLTEXT index may be added at a time when ALGORITHM is set to `NOCOPY`.

This operation supports a read-only locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `SHARED`. When this strategy is used, read-only concurrent DML is permitted.

For example, this succeeds, but the first operation requires the table to be rebuilt ALGORITHM set to `INPLACE`, so that the hidden `FTS_DOC_ID` column can be added:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.043 sec)

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ADD FULLTEXT INDEX c_index (c);
Query OK, 0 rows affected (0.017 sec)
```

And this succeeds in the same way as above:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
CREATE FULLTEXT INDEX b_index ON tab (b);
Query OK, 0 rows affected (0.048 sec)

SET SESSION alter_algorithm='NOCOPY';
CREATE FULLTEXT INDEX c_index ON tab (c);
Query OK, 0 rows affected (0.016 sec)
```

But this second command fails, because only one FULLTEXT index can be added at a time:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d VARCHAR(50)
);

SET SESSION alter_algorithm='INPLACE';
ALTER TABLE tab ADD FULLTEXT INDEX b_index (b);
Query OK, 0 rows affected (0.041 sec)

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ADD FULLTEXT INDEX c_index (c), ADD FULLTEXT INDEX d_index (d);
ERROR 1846 (0A000): ALGORITHM=NOCOPY is not supported. Reason: InnoDB presently supports one FULLTEXT
index creation at a time. Try ALGORITHM=COPY
```

Adding a Spatial Index

InnoDB supports adding a SPATIAL index to a table with ALGORITHM set to `NOCOPY`.

This operation supports a read-only locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `SHARED`. When this strategy is used, read-only concurrent DML is permitted.

For example, this succeeds:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c GEOMETRY NOT NULL
);

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ADD SPATIAL INDEX c_index (c);
Query OK, 0 rows affected (0.005 sec)
```

And this succeeds in the same way as above:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c GEOMETRY NOT NULL
);

SET SESSION alter_algorithm='NOCOPY';
CREATE SPATIAL INDEX c_index ON tab (c);
Query OK, 0 rows affected (0.005 sec)
```

`ALTER TABLE ... DROP INDEX` and `DROP INDEX`

InnoDB supports dropping indexes from a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … DROP INDEX and DROP INDEX for more information.

This applies to ALTER TABLE … DROP INDEX and DROP INDEX for InnoDB tables.

`ALTER TABLE ... ADD FOREIGN KEY`

InnoDB does supports adding foreign key constraints to a table with ALGORITHM set to `NOCOPY`. In order to add a new foreign key constraint to a table with ALGORITHM set to `NOCOPY`, the foreign_key_checks system variable needs to be set to `OFF`. If it is set to `ON`, then `ALGORITHM=COPY` is required.

This operation supports the non-locking strategy. This strategy can be explicitly chosen by setting the LOCK clause to `NONE`. When this strategy is used, all concurrent DML is permitted.

For example, this fails:

```
CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT
);

CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab1 ADD FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a);
ERROR 1846 (0A000): ALGORITHM=NOCOPY is not supported. Reason: Adding foreign keys needs
foreign_key_checks=OFF. Try ALGORITHM=COPY
```

But this succeeds:

```
CREATE OR REPLACE TABLE tab1 (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50),
   d INT
);

CREATE OR REPLACE TABLE tab2 (
   a INT PRIMARY KEY,
   b VARCHAR(50)
);

SET SESSION foreign_key_checks=OFF;
SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab1 ADD FOREIGN KEY tab2_fk (d) REFERENCES tab2 (a);
Query OK, 0 rows affected (0.011 sec)
```

This applies to ALTER TABLE … ADD FOREIGN KEY for InnoDB tables.

`ALTER TABLE ... DROP FOREIGN KEY`

InnoDB supports dropping foreign key constraints from a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … DROP FOREIGN KEY for more information.

This applies to ALTER TABLE … DROP FOREIGN KEY for InnoDB tables.

Table Operations

`ALTER TABLE ... AUTO_INCREMENT=...`

InnoDB supports changing a table's AUTO_INCREMENT value with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … AUTO_INCREMENT=… for more information.

This applies to ALTER TABLE … AUTO_INCREMENT=… for InnoDB tables.

`ALTER TABLE ... ROW_FORMAT=...`

InnoDB does **not** support changing a table's row format with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=DYNAMIC;

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ROW_FORMAT=COMPRESSED;
ERROR 1846 (0A000): ALGORITHM=NOCOPY is not supported. Reason: Changing table options requires the table
to be rebuilt. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … ROW_FORMAT=… for InnoDB tables.

`ALTER TABLE ... KEY_BLOCK_SIZE=...`

InnoDB does **not** support changing a table's KEY_BLOCK_SIZE with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) ROW_FORMAT=COMPRESSED
  KEY_BLOCK_SIZE=4;

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab KEY_BLOCK_SIZE=2;
ERROR 1846 (0A000): ALGORITHM=NOCOPY is not supported. Reason: Changing table options requires the table
to be rebuilt. Try ALGORITHM=INPLACE
```

This applies to KEY_BLOCK_SIZE=… for InnoDB tables.

`ALTER TABLE ... PAGE_COMPRESSED=1` and `ALTER TABLE ... PAGE_COMPRESSION_LEVEL=...`

In MariaDB 10.3.10 and later, InnoDB supports setting a table's PAGE_COMPRESSED value to `1` with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

InnoDB does **not** support changing a table's PAGE_COMPRESSED value from `1` to `0` with ALGORITHM set to `NOCOPY`.

In these versions, InnoDB also supports changing a table's PAGE_COMPRESSION_LEVEL value with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause is set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … PAGE_COMPRESSED=1 and ALTER TABLE … PAGE_COMPRESSION_LEVEL=… for more information.

This applies to ALTER TABLE … PAGE_COMPRESSED=… and ALTER TABLE … PAGE_COMPRESSION_LEVEL=… for InnoDB tables.

`ALTER TABLE ... DROP SYSTEM VERSIONING`

InnoDB does **not** support dropping system versioning from a table with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
) WITH SYSTEM VERSIONING;

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab DROP SYSTEM VERSIONING;
ERROR 1845 (0A000): ALGORITHM=NOCOPY is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … DROP SYSTEM VERSIONING for InnoDB tables.

`ALTER TABLE ... DROP CONSTRAINT`

In MariaDB 10.3.6 and later, InnoDB supports dropping a CHECK constraint from a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … DROP CONSTRAINT for more information.

This applies to ALTER TABLE … DROP CONSTRAINT for InnoDB tables.

`ALTER TABLE ... FORCE`

InnoDB does **not** support forcing a table rebuild with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab FORCE;
ERROR 1845 (0A000): ALGORITHM=NOCOPY is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … FORCE for InnoDB tables.

`ALTER TABLE ... ENGINE=InnoDB`

InnoDB does **not** support forcing a table rebuild with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SET SESSION alter_algorithm='NOCOPY';
ALTER TABLE tab ENGINE=InnoDB;
ERROR 1845 (0A000): ALGORITHM=NOCOPY is not supported for this operation. Try ALGORITHM=INPLACE
```

This applies to ALTER TABLE … ENGINE=InnoDB for InnoDB tables.

`OPTIMIZE TABLE ...`

InnoDB does **not** support optimizing a table with ALGORITHM set to `NOCOPY`.

For example:

```
CREATE OR REPLACE TABLE tab (
   a INT PRIMARY KEY,
   b VARCHAR(50),
   c VARCHAR(50)
);

SHOW GLOBAL VARIABLES WHERE Variable_name IN('innodb_defragment', 'innodb_optimize_fulltext_only');
+--------------------------------+-------+
| Variable_name                  | Value |
+--------------------------------+-------+
| innodb_defragment              | OFF   |
| innodb_optimize_fulltext_only | OFF   |
+--------------------------------+-------+
2 rows in set (0.001 sec)

SET SESSION alter_algorithm='NOCOPY';
OPTIMIZE TABLE tab;
+---------+----------+----------+-------------------------------------------------------------------------------
-----+
| Table   | Op       | Msg_type | Msg_text
|
+---------+----------+----------+-------------------------------------------------------------------------------
-----+
| db1.tab | optimize | note     | Table does not support optimize, doing recreate + analyze instead
|
| db1.tab | optimize | error    | ALGORITHM=NOCOPY is not supported for this operation. Try
ALGORITHM=INPLACE |
| db1.tab | optimize | status   | Operation failed
|
+---------+----------+----------+-------------------------------------------------------------------------------
-----+
3 rows in set, 1 warning (0.002 sec)
```

This applies to OPTIMIZE TABLE for InnoDB tables.

`ALTER TABLE ... RENAME TO` and `RENAME TABLE ...`

InnoDB supports renaming a table with ALGORITHM set to `NOCOPY` in the cases where the operation supports having the ALGORITHM clause set to `INSTANT`.

See InnoDB Online DDL Operations with ALGORITHM=INSTANT: ALTER TABLE … RENAME TO and RENAME TABLE … for more information.

This applies to ALTER TABLE … RENAME TO and RENAME TABLE for InnoDB tables.

Limitations

Limitations Related to Generated (Virtual and Persistent/Stored) Columns

Generated columns do not currently support online DDL for all of the same operations that are supported for "real" columns.

See Generated (Virtual and Persistent/Stored) Columns: Statement Support for more information on the limitations.

This page is licensed: CC BY-SA / Gnu FDL

Instant ADD COLUMN for InnoDB

Normally, adding a column to a table requires the full table to be rebuilt. The complexity of the operation is proportional to the size of the table, or O(n·m) where n is the number of rows in the table and m is the number of indexes.

In MariaDB 10.0 and later, the ALTER TABLE statement supports online DDL for storage engines that have implemented the relevant online DDL algorithms and locking strategies.

The InnoDB storage engine has implemented online DDL for many operations. These online DDL optimizations allow concurrent DML to the table in many cases, even if the table needs to be rebuilt.

See InnoDB Online DDL Overview for more information about online DDL with InnoDB.

Allowing concurrent DML during the operation does not solve all problems. When a column was added to a table with the older in-place optimization, the resulting table rebuild could still significantly increase the I/O and memory consumption and cause replication lag.

In contrast, with the new instant ALTER TABLE … ADD COLUMN, all that is needed is an O(1) operation to insert a special hidden record into the table, and an update of the data dictionary. For a large table, instead of taking several hours, the operation would be completed in the blink of an eye. The ALTER TABLE … ADD COLUMN operation is only slightly more expensive than a regular INSERT, due to locking constraints.

In the past, some developers may have implemented a kind of "instant add column" in the application by encoding multiple columns in a single TEXT or BLOB column. MariaDB Dynamic Columns was an early example of that. A more recent example is JSON and related string manipulation functions.

Adding real columns has the following advantages over encoding columns into a single "expandable" column:

- Efficient storage in a native binary format
- Data type safety
- Indexes can be built natively
- Constraints are available: UNIQUE, CHECK, FOREIGN KEY
- DEFAULT values can be specified
- Triggers can be written more easily

With instant ALTER TABLE … ADD COLUMN, you can enjoy all the benefits of structured storage without the drawback of having to rebuild the table.

Instant ALTER TABLE … ADD COLUMN is available for both old and new InnoDB tables. Basically you can just upgrade from MySQL 5.x or MariaDB and start adding columns instantly.

Columns instantly added to a table exist in a separate data structure from the main table definition, similar to how InnoDB separates `BLOB` columns. If the table ever becomes empty, (such as from TRUNCATE or DELETE statements), InnoDB incorporates the instantly added columns into the main table definition. See InnoDB Online DDL Operations with ALGORITHM=INSTANT: Non-canonical Storage Format Caused by Some Operations for more information.

The operation is also crash safe. If the server is killed while executing an instant ALTER TABLE … ADD COLUMN, when the table is restored InnoDB integrates the new column, flattening the table definition.

Limitations

- In MariaDB 10.3, instant ALTER TABLE … ADD COLUMN only applies when the added columns appear last in the table. The place specifier `LAST` is the default. If `AFTER` col is specified, then col must be the last column, or the operation will require the table to be rebuilt. In MariaDB 10.4, this restriction was lifted.
- If the table contains a hidden `FTS_DOC_ID` column due to a FULLTEXT INDEX, then instant ALTER TABLE … ADD COLUMN will not be possible.
- InnoDB data files after instant ALTER TABLE … ADD COLUMN cannot be imported to older versions of MariaDB or MySQL without first being rebuilt.
- After using Instant ALTER TABLE … ADD COLUMN, any table-rebuilding operation such as ALTER TABLE … FORCE will incorporate instantaneously added columns into the main table body.
- Instant ALTER TABLE … ADD COLUMN is not available for ROW_FORMAT=COMPRESSED.
- In MariaDB 10.3, ALTER TABLE … DROP COLUMN requires the table to be rebuilt. In MariaDB 10.4, this restriction was lifted.

Example

```
CREATE TABLE t(id INT PRIMARY KEY, u INT UNSIGNED NOT NULL UNIQUE)
ENGINE=InnoDB;

INSERT INTO t(id,u) VALUES(1,1),(2,2),(3,3);

ALTER TABLE t ADD COLUMN
(d DATETIME DEFAULT current_timestamp(),
 p POINT NOT NULL DEFAULT ST_GeomFromText('POINT(0 0)'),
 t TEXT CHARSET utf8 DEFAULT 'The quick brown fox jumps over the lazy dog');

UPDATE t SET t=NULL WHERE id=3;

SELECT id,u,d,ST_AsText(p),t FROM t;

SELECT variable_value FROM information_schema.global_status
WHERE variable_name = 'innodb_instant_alter_column';
```

The above example illustrates that when the added columns are declared NOT NULL, a DEFAULT value must be available, either implied by the data type or set explicitly by the user. The expression need not be constant, but it must not refer to the columns of the table, such as DEFAULT u+1 (a MariaDB extension). The DEFAULT current_timestamp() would be evaluated at the time of the ALTER TABLE and apply to each row, like it does for non-instant ALTER TABLE. If a subsequent ALTER TABLE changes the DEFAULT value for subsequent INSERT, the values of the columns in existing records will naturally be unaffected.

The design was brainstormed in April by engineers from MariaDB Corporation, Alibaba and Tencent. A prototype was developed by Vin Chen (□□□) from the Tencent Game DBA Team.

InnoDB Row Formats

See InnoDB Row Formats Overview.

An overview of the four InnoDB row formats (REDUNDANT, COMPACT, DYNAMIC, COMPRESSED), comparing their storage efficiency and feature support.

See InnoDB COMPACT Row Format.

Detailed information on the COMPACT row format, which reduces storage space by roughly 20% compared to REDUNDANT, handling NULLs and variable-length columns efficiently.

See InnoDB COMPRESSED Row Format.

Learn about the COMPRESSED row format, which compresses data and index pages using algorithms like zlib to minimize storage footprint at the cost of CPU.

See InnoDB DYNAMIC Row Format.

The DYNAMIC row format, default in modern MariaDB versions, optimizes storage for large BLOB/TEXT columns by storing them on separate overflow pages.

See InnoDB REDUNDANT Row Format.

Information on the legacy REDUNDANT row format, primarily maintained for backward compatibility with older MySQL versions.

See Troubleshooting Row Size Too Large Errors with InnoDB.

Complete InnoDB row size troubleshooting: innodb_strict_mode, ALTER TABLE ROW_FORMAT=DYNAMIC, VARCHAR/VARBINARY(256) overflow, and BLOB/TEXT solutions.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Row Formats Overview

The InnoDB storage engine supports four different row formats:

- REDUNDANT
- COMPACT
- DYNAMIC
- COMPRESSED

Default Row Format

The innodb_default_row_format system variable can be used to set the default row format for InnoDB tables. The possible values are:

- `redundant`
- `compact`
- `dynamic`

This system variable's default value is `dynamic`, which means that the default row format is `DYNAMIC`.

This system variable cannot be set to `compressed`, which means that the default row format cannot be `COMPRESSED`.

For example, the following statements would create a table with the `DYNAMIC` row format:

```
SET SESSION innodb_strict_mode=ON;

SET GLOBAL innodb_default_row_format='dynamic';

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB;
```

Setting a Table's Row Format

One way to specify an InnoDB table's row format is by setting the ROW_FORMAT table option to the relevant row format in a CREATE TABLE or ALTER TABLE statement:

```
SET SESSION innodb_strict_mode=ON;

SET GLOBAL innodb_file_per_table=ON;

SET GLOBAL innodb_file_format='Barracuda';

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB ROW_FORMAT=DYNAMIC;
```

Checking a Table's Row Format

The SHOW TABLE STATUS statement can be used to see the row format used by a table:

```
SHOW TABLE STATUS FROM db1 WHERE Name='tab'\G
*************************** 1. row ***************************
           Name: tab
         Engine: InnoDB
        Version: 10
     Row_format: Dynamic
           Rows: 0
 Avg_row_length: 0
    Data_length: 16384
Max_data_length: 0
   Index_length: 0
      Data_free: 0
 Auto_increment: NULL
    Create_time: 2019-04-18 20:24:04
    Update_time: NULL
     Check_time: NULL
      Collation: latin1_swedish_ci
       Checksum: NULL
 Create_options: row_format=DYNAMIC
        Comment:
```

The information_schema.INNODB_SYS_TABLES table can also be queried to see the row format used by a table:

```
SELECT * FROM information_schema.INNODB_SYS_TABLES WHERE name='db1/tab'\G
*************************** 1. row ***************************
     TABLE_ID: 42
         NAME: db1/tab
         FLAG: 33
       N_COLS: 4
        SPACE: 27
  FILE_FORMAT: Barracuda
   ROW_FORMAT: Dynamic
ZIP_PAGE_SIZE: 0
   SPACE_TYPE: Single
```

A table's tablespace is tagged with the lowest InnoDB file format that supports the table's row format. So, even if the `Barracuda` file format is enabled, tables that use the `COMPACT` or `REDUNDANT` row formats are tagged with the `Antelope` file format in the information_schema.INNODB_SYS_TABLES table.

Row Formats

REDUNDANT Row Format

The `REDUNDANT` row format is the original non-compacted row format.

The `REDUNDANT` row format was the only available row format before MySQL 5.0.3. In that release, this row format was retroactively named the `REDUNDANT` row format. In the same release, the `COMPACT` row format was introduced as the new default row format.

See InnoDB REDUNDANT Row Format for more information.

COMPACT Row Format

Default row format in earlier versions `COMPACT`.

The `COMPACT` row format is similar to the `REDUNDANT` row format, but it stores data in a more compact manner that requires about 20% less storage.

See InnoDB COMPACT Row Format for more information.

DYNAMIC Row Format

`DYNAMIC` is the default row format.

The `DYNAMIC` row format is similar to the `COMPACT` row format, but tables using the `DYNAMIC` row format can store even more data on overflow pages than tables using the `COMPACT` row format. This results in more efficient data storage than tables using the `COMPACT` row format, especially for tables containing columns using the VARBINARY, VARCHAR, BLOB and TEXT data types. However, InnoDB tables using the `COMPRESSED` row format are more efficient.

See InnoDB DYNAMIC Row Format for more information.

COMPRESSED Row Format

An alternative way to compress InnoDB tables is by using InnoDB Page Compression.

The `COMPRESSED` row format is similar to the `COMPACT` row format, but tables using the `COMPRESSED` row format can store even more data on overflow pages than tables using the `COMPACT` row format. This results in more efficient data storage than tables using the `COMPACT` row format, especially for tables containing columns using the VARBINARY, VARCHAR, BLOB and TEXT data types.

The `COMPRESSED` row format also supports compression of all data and index pages.

See InnoDB COMPRESSED Row Format for more information.

Maximum Row Size

Several factors help determine the maximum row size of an InnoDB table.

First, MariaDB enforces a 65,535 byte limit on a table's maximum row size. The total size of a table's BLOB and TEXT columns do not count towards this limit. Only the pointers for a table's BLOB and TEXT columns count towards this limit. MariaDB enforces this limit for all storage engines, so this limit also applies to InnoDB tables. Therefore, this limit is the absolute maximum row size for an InnoDB table.

If you try to create a table that exceeds MariaDB's global limit on a table's maximum row size, then you will see an error like this:

```
ERROR 1118 (42000): Row size too large. The maximum row size for the used table type,
not counting BLOBs, is 65535. This includes storage overhead, check the manual. You
have to change some columns to TEXT or BLOBs
```

However, InnoDB also has its own limits on the maximum row size, so an InnoDB table's maximum row size could be smaller than MariaDB's global limit.

Second, the maximum amount of data that an InnoDB table can store in a row's main data page depends on the value of the innodb_page_size system variable. At most, the data that a single row can consume on the row's main data page is half of the value of the innodb_page_size system variable. With the default value of `16k`, that would mean that a single row can consume at most around 8 KB on the row's main data page. However, the limit on the row's main data page is not the absolute limit on the row's size.

Third, all InnoDB row formats can store certain kinds of data in overflow pages, so the maximum row size of an InnoDB table can be larger than the maximum amount of data that can be stored in the row's main data page.

Some row formats can store more data in overflow pages than others. For example, the `DYNAMIC` and `COMPRESSED` row formats can store the most data in overflow pages. To see how to determine the how the various InnoDB row formats can use overflow pages, see the following sections:

- InnoDB REDUNDANT Row Format: Overflow Pages with the REDUNDANT Row Format
- InnoDB COMPACT Row Format: Overflow Pages with the COMPACT Row Format
- InnoDB DYNAMIC Row Format: Overflow Pages with the DYNAMIC Row Format
- InnoDB COMPRESSED Row Format: Overflow Pages with the COMPRESSED Row Format

If a table's definition can allow rows that the table's InnoDB row format can't actually store, then InnoDB will raise errors or warnings in certain scenarios.

If the table were using the `REDUNDANT` or `COMPACT` row formats, then the error or warning would be the following:

```
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT or BLOB or using ROW_FORMAT=DYNAMIC or ROW_FORMAT=COMPRESSED
may help. In current row format, BLOB prefix of 768 bytes is stored inline.
```

And if the table were using the `DYNAMIC` or `COMPRESSED` row formats, then the error or warning would be the following:

```
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT or BLOB may help. In current row format, BLOB prefix of 0 bytes is stored inline.
```

These messages are raised in the following cases:

- If InnoDB strict mode is enabled and if a DDL statement is executed that touches the table, such as CREATE TABLE or ALTER TABLE, then InnoDB will raise an error with this message
- If InnoDB strict mode is disabled and if a DDL statement is executed that touches the table, such as CREATE TABLE `or [ALTER TABLE](#pg-ence-sql-statements-data-definition-alter-alter-table-readme-a2aa59e4)`, then InnoDB will raise a warning with this message.
- Regardless of whether InnoDB strict mode is enabled, if a DML statement is executed that attempts to write a row that the table's InnoDB row format can't store, then InnoDB will raise an error with this message.

For information on how to solve the problem, see Troubleshooting Row Size Too Large Errors with InnoDB.

Feature Summary

Feature	Dynamic	Compressed	Compact	Redundant
Default	Yes	No	No	No
Recommended	Yes	No	No	No
Efficiently stores large columns	Yes	Yes	No	No
Efficiently utilizes buffer pool	Yes	No	Yes	Yes
Supported Page Sizes	• 64k • 32k • 16k • 8k • 4k	• 16k • 8k • 4k	• 64k • 32k • 16k • 8k • 4k	• 64k • 32k • 16k • 8k • 4k
Maximum size of indexed column values	• 3072 bytes (innodb_page_size >= 16k) • 1536 bytes (innodb_page_size == 8k) • 768 bytes (innodb_page_size == 4k)	• 3072 bytes (innodb_page_size >= 16k) • 1536 bytes (innodb_page_size == 8k) • 768 bytes (innodb_page_size == 4k)	767 bytes	767 bytes
Supports ADD/DROP column with INSTANT Algorithm	Yes	No	Yes	Yes

Known Issues

Upgrading Causes Row Size Too Large Errors

In earlier versions, MariaDB doesn't properly calculate the row sizes while executing DDL. In these versions, *unsafe* tables can be created, even if InnoDB strict mode is enabled. The calculations were fixed by MDEV-19292.

As a side effect, some tables that could be created or altered in previous versions may get rejected with the following error in these releases and any later releases.

```
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT or BLOB may help. In current row format, BLOB prefix of 0 bytes is stored inline.
```

And users could also see the following message as an error or warning in the error log:

```
[Warning] InnoDB: Cannot add field col in table db1.tab because after adding it, the row size is 8478
which is greater than maximum allowed size (8126) for a record on index leaf page.
```

InnoDB used the wrong calculations to determine row sizes for quite a long time, so a lot of users may unknowingly have *unsafe* tables that the InnoDB row format can't actually store.

InnoDB does not currently have an easy way to check which existing tables have this problem. See MDEV-20400 for more information.

For information on how to solve the problem, see Troubleshooting Row Size Too Large Errors with InnoDB.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB COMPACT Row Format

Note `COMPACT` was the default row format in prior versions of MariaDB. MariaDB has since transitioned to `DYNAMIC` as the default row format.

The `COMPACT` row format is similar to the `REDUNDANT` row format, but it stores data in a more compact manner that requires about 20% less storage.

Using the `COMPACT` Row Format

- If you performed a physical upgrade from older version of MariaDB Server or MySQL to a newer MariaDB Server version, then some of your tables may still use COMPACT row format.
- Compact row format does not store large columns as efficiently as the Dynamic row format.
- Compact row format limits indexing column values to 767 bytes, which is significant smaller than the Dynamic row format.

The easiest way to create an InnoDB table that uses the `COMPACT` row format is by setting the ROW_FORMAT table option to `COMPACT` in a CREATE TABLE or ALTER TABLE statement.

It is recommended to set the innodb_strict_mode system variable to `ON` when using this row format.

The `COMPACT` row format is supported by both the `Antelope` and the `Barracuda` file formats, so tables with this row format can be created regardless of the value of the innodb_file_format system variable.

For example:

```
SET SESSION innodb_strict_mode=ON;

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB ROW_FORMAT=COMPACT;
```

Index Prefixes with the `COMPACT` Row Format

The `COMPACT` row format supports index prefixes up to 767 bytes.

Overflow Pages with the `COMPACT` Row Format

All InnoDB row formats can store certain kinds of data in overflow pages. This allows for the maximum row size of an InnoDB table to be larger than the maximum amount of data that can be stored in the row's main data page. See Maximum Row Size for more information about the other factors that can contribute to the maximum row size for InnoDB tables.

In the `COMPACT` row format variable-length columns, such as columns using the VARBINARY, VARCHAR, BLOB and TEXT data types, can be partially stored in overflow pages.

InnoDB only considers using overflow pages if the table's row size is greater than half of innodb_page_size. If the row size is greater than this, then InnoDB chooses variable-length columns to be stored on overflow pages until the row size is less than half of innodb_page_size.

For VARBINARY, VARCHAR, BLOB and TEXT columns, only values longer than 767 bytes are considered for storage on overflow pages. Bytes that are stored to track a value's length do not count towards this limit. This limit is only based on the length of the actual column's data.

Fixed-length columns greater than 767 bytes are encoded as variable-length columns, so they can also be stored in overflow pages if the table's row size is greater than half of innodb_page_size. Even though a column using the CHAR data type can hold at most 255 characters, a CHAR column can still exceed 767 bytes in some cases. For example, a `char(255)` column can exceed 767 bytes if the character set is `utf8mb4`.

If a column is chosen to be stored on overflow pages, then the first 767 bytes of the column's value and a 20-byte pointer to the column's first overflow page are stored on the main page. Each overflow page is the size of innodb_page_size. If a column is too large to be stored on a single overflow page, then it is stored on multiple overflow pages. Each overflow page contains part of the data and a 20-byte pointer to the next overflow page, if a next page exists.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB COMPRESSED Row Format

An alternative (and usually superior) way to compress InnoDB tables is by using InnoDB Page Compression. See Comparison with the COMPRESSED Row Format.

The `COMPRESSED` row format is similar to the `COMPACT` row format, but tables using the `COMPRESSED` row format can store even more data on overflow pages than tables using the `COMPACT` row format. This results in more efficient data storage than tables using the `COMPACT` row format, especially for tables containing columns using the VARBINARY, VARCHAR, BLOB and TEXT data types.

The `COMPRESSED` row format also supports compression of all data and index pages.

Supported Block Sizes

The Compressed row format supports the following block sizes:

Block Size	KEY_BLOCK_SIZE Value
1 KB	1
2 KB	2
4 KB	4
8 KB	8
16 KB	16

If the `KEY_BLOCK_SIZE` table option is not specified, the block size defaults to half of innodb_page_size. With the default 16 KB page size, the block size defaults to 8 KB.

For compression to be effective, the chosen block size should be smaller than the servers value of the innodb_page_size system variable.

Supported Index Prefix Limits

The limit for indexing column values depends on the innodb_page_size value:

Page Size	Index Prefix Limit
16k	3072 bytes
8k	1536 bytes
4k	768 bytes

Using the `COMPRESSED` Row Format

The Compressed row format does not efficiently use the InnoDB buffer pool, so it is not the recommended way to achieve InnoDB table compression. For more information about how to compress InnoDB tables, see Configure InnoDB Page Compression.

An InnoDB table that uses the `COMPRESSED` row format can be created by setting the ROW_FORMAT table option to `COMPRESSED` and by setting the KEY_BLOCK_SIZE table option to one of the following values in a CREATE TABLE or ALTER TABLE statement, where the units are in `KB`.

`16k` is the default value of the innodb_page_size system variable, so using `16` will usually result in minimal compression unless one of the following is true:

- The table has many columns that can be stored in overflow pages, such as columns that use the VARBINARY, VARCHAR, BLOB and TEXT data types.
- The server is using a non-default innodb_page_size value that is greater than `16k`.

The value of the innodb_page_size system variable can be set to `32k` and `64k`. This is especially useful because the larger page size permits more columns using the VARBINARY, VARCHAR, BLOB and TEXT data types. Regardless, even when the value of the innodb_page_size system variable is set to some value higher than `16k`, `16` is still the maximum value for the KEY_BLOCK_SIZE table option for InnoDB tables using the `COMPRESSED` row format.

The `COMPRESSED` row format cannot be set as the default row format with the innodb_default_row_format system variable.

The `COMPRESSED` row format is only supported by the `Barracuda` file format. In earlier versions, the `COMPRESSED` row format is only supported if the InnoDB file format is `Barracuda`. Therefore, the innodb_file_format system variable must be set to `Barracuda` to use these row formats in those versions.

In earlier versions, the `COMPRESSED` row format is also only supported if the table is in a file per-table tablespace. Therefore, the innodb_file_per_table system variable must be set to `ON` to use this row format in those versions.

It is also recommended to set the innodb_strict_mode system variable to `ON` when using this row format.

InnoDB automatically uses the `COMPRESSED` row format for a table if the KEY_BLOCK_SIZE table option is set to some value in a CREATE TABLE or ALTER TABLE statement:

```
SET SESSION innodb_strict_mode=ON;

SET GLOBAL innodb_file_per_table=ON;

SET GLOBAL innodb_file_format='Barracuda';

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB KEY_BLOCK_SIZE=4;
```

If the KEY_BLOCK_SIZE table option is **not** set to some value, but the ROW_FORMAT table option is set to `COMPRESSED` in a CREATE TABLE or ALTER TABLE statement, then InnoDB uses a default value of `8` for the KEY_BLOCK_SIZE table option:

```
SET SESSION innodb_strict_mode=ON;

SET GLOBAL innodb_file_per_table=ON;

SET GLOBAL innodb_file_format='Barracuda';

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB ROW_FORMAT=COMPRESSED;
```

Create an InnoDB Table with the Compressed Row Format using ROW_FORMAT

The default block size for tables that use the Compressed row format is half of innodb_page_size. With the default 16 KB page size, the block size defaults to 8 KB. A compressed table with the default block size can be created by setting the ROW_FORMAT table option to COMPRESSED:

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
) ROW_FORMAT = Compressed;
```

Step-by-Step Procedure

1. Connect to the server using MariaDB Client:

```
$ mariadb --user=root
```

2. Confirm that the default storage engine is InnoDB by checking the default_storage_engine system variable using the SHOW SESSION VARIABLES statement:

```
SHOW SESSION VARIABLES
   LIKE 'default_storage_engine';
```

```
+------------------------+--------+
| Variable_name          | Value  |
+------------------------+--------+
| default_storage_engine | InnoDB |
+------------------------+--------+
```

3. Create the table using the CREATE TABLE statement, and specify the Compressed row format using the `ROW_FORMAT` table option:

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
) ROW_FORMAT = Compressed;
```

4. Confirm that the table uses the Compressed row format with an 8 KB block size by querying the information_schema.INNODB_SYS_TABLES table:

```
SELECT NAME, ROW_FORMAT, ZIP_PAGE_SIZE
FROM information_schema.INNODB_SYS_TABLES
WHERE NAME='hq_sales/invoices';
```

```
+-------------------+------------+---------------+
| NAME              | ROW_FORMAT | ZIP_PAGE_SIZE |
+-------------------+------------+---------------+
| hq_sales/invoices | Compressed |          8192 |
+-------------------+------------+---------------+
```

Create an InnoDB Table with the Compressed Row Format using KEY_BLOCK_SIZE

The default block size for tables that use the Compressed row format is half of innodb_page_size. With the default 16 KB page size, the block size defaults to 8 KB. A compressed table with a non-default block size can be created by setting the `KEY_BLOCK_SIZE` table option to the desired block size.

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
) KEY_BLOCK_SIZE = 4;
```

Step-by-Step Procedure

1. Connect to the server using MariaDB Client:

```
$ mariadb --user=root
```

2. Confirm that the default storage engine is InnoDB by checking the default_storage_engine system variable using the SHOW SESSION VARIABLES statement:

```
SHOW SESSION VARIABLES
   LIKE 'default_storage_engine';
```

```
+------------------------+--------+
| Variable_name          | Value  |
+------------------------+--------+
| default_storage_engine | InnoDB |
+------------------------+--------+
```

3. Create the table using the CREATE TABLE statement, and specify the block size using the `KEY_BLOCK_SIZE` table option, which implies the Compressed row format:

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
) KEY_BLOCK_SIZE = 4;
```

4. Confirm that the table uses the Compressed row format with an 8 KB block size by querying the information_schema.INNODB_SYS_TABLES table:

```
SELECT NAME, ROW_FORMAT, ZIP_PAGE_SIZE
FROM information_schema.INNODB_SYS_TABLES
WHERE NAME='hq_sales/invoices';
```

```
+-------------------+------------+---------------+
| NAME              | ROW_FORMAT | ZIP_PAGE_SIZE |
+-------------------+------------+---------------+
| hq_sales/invoices | Compressed |          4096 |
+-------------------+------------+---------------+
```

Compression with the `COMPRESSED` Row Format

The `COMPRESSED` row format supports compression of all data and index pages.

To avoid compressing and uncompressing pages too many times, InnoDB tries to keep both compressed and uncompressed pages in the buffer pool when there is enough room. This results in a bigger cache. When there is

not enough room, an adaptive LRU algorithm is used to decide whether compressed or uncompressed pages should be evicted from the buffer: for CPU-bound workloads, the compressed pages are evicted first; for I/O-bound workloads, the uncompressed pages are evicted first. Of course, when necessary, both the compressed and uncompressed version of the same data can be evicted from the buffer.

Each compressed page has an uncompressed *modification log*, stored within the page itself. InnoDB writes small changes into it. When the space in the modification log runs out, the page is uncompressed, changes are applied, and the page is recompressed again. This is done to avoid some unnecessary decompression and compression operations.

Sometimes a *compression failure* might happen, because the data has grown too much to fit the page. When this happens, the page (and the index node) is split into two different pages. This process can be repeated recursively until the data fit the pages. This can be CPU-consuming on some busy servers which perform many write operations.

Before writing a compressed page into a data file, InnoDB writes it into the redo log. This ensures that the redo log can always be used to recover tables after a crash, even if the compression library is updated and some incompatibilities are introduced. But this also means that the redo log will grow faster and might need more space, or the frequency of checkpoints might need to increase.

Monitoring Performance of the `COMPRESSED` Row Format

The following `INFORMATION_SCHEMA` tables can be used to monitor the performances of InnoDB compressed tables:

- INNODB_CMP and INNODB_CMP_RESET
- INNODB_CMP_PER_INDEX and INNODB_CMP_PER_INDEX_RESET
- INNODB_CMPMEM and INNODB_CMPMEM_RESET

Index Prefixes with the `COMPRESSED` Row Format

The `COMPRESSED` row format supports index prefixes up to 3072 bytes. In MariaDB 10.2 and before, the innodb_large_prefix system variable is used to configure the maximum index prefix length. In these versions, if innodb_large_prefix is set to `ON`, then the maximum prefix length is 3072 bytes, and if it is set to `OFF`, then the maximum prefix length is 767 bytes.

Overflow Pages with the `COMPRESSED` Row Format

All InnoDB row formats can store certain kinds of data in overflow pages. This allows for the maximum row size of an InnoDB table to be larger than the maximum amount of data that can be stored in the row's main data page. See Maximum Row Size for more information about the other factors that can contribute to the maximum row size for InnoDB tables.

In the `COMPRESSED` row format variable-length columns, such as columns using the VARBINARY, VARCHAR, BLOB and TEXT data types, can be completely stored in overflow pages.

InnoDB only considers using overflow pages if the table's row size is greater than half of innodb_page_size. If the row size is greater than this, then InnoDB chooses variable-length columns to be stored on overflow pages until the row size is less than half of innodb_page_size.

For BLOB and TEXT columns, only values longer than 40 bytes are considered for storage on overflow pages. For VARBINARY and VARCHAR columns, only values longer than 255 bytes are considered for storage on overflow pages. Bytes that are stored to track a value's length do not count towards these limits. These limits are only based on the length of the actual column's data.

These limits differ from the limits for the `COMPACT` row format, where the limit is 767 bytes for all types.

Fixed-length columns greater than 767 bytes are encoded as variable-length columns, so they can also be stored in overflow pages if the table's row size is greater than half of innodb_page_size. Even though a column using the CHAR data type can hold at most 255 characters, a CHAR column can still exceed 767 bytes in some cases. For example, a `char(255)` column can exceed 767 bytes if the character set is `utf8mb4`.

If a column is chosen to be stored on overflow pages, then the entire value of the column is stored on overflow pages, and only a 20-byte pointer to the column's first overflow page is stored on the main page. Each overflow page is the size of innodb_page_size. If a column is too large to be stored on a single overflow page, then it is stored on multiple overflow pages. Each overflow page contains part of the data and a 20-byte pointer to the next overflow page, if a next page exists.

This behavior differs from the behavior of the `COMPACT` row format, which always stores the column prefix on the main page. This allows tables using the `COMPRESSED` row format to contain a high number of columns using the VARBINARY, VARCHAR, BLOB and TEXT data types.

Read-Only

MariaDB starting with 10.6

From MariaDB 10.6.0 until MariaDB 10.6.5, tables that are of the `COMPRESSED` row format are read-only by default. This was intended to be the first step towards removing write support and deprecating the feature.
This plan has been scrapped, and from MariaDB 10.6.6, `COMPRESSED` tables are no longer read-only by default.
From MariaDB 10.6.0 to MariaDB 10.6.5, set the innodb_read_only_compressed variable to `OFF` to make the tables writable.

InnoDB DYNAMIC Row Format

`DYNAMIC` is the default InnoDB row format.

The `DYNAMIC` row format is similar to the `COMPACT` row format, but tables using the `DYNAMIC` row format can store even more data on overflow pages than tables using the `COMPACT` row format. This results in more efficient data storage than tables using the `COMPACT` row format, especially for tables containing columns using the VARBINARY, VARCHAR, BLOB and TEXT data types. While InnoDB tables using the `COMPRESSED` row format can result in even greater space-efficiency, COMPRESSED requires substantially more memory and CPU to both read and write, so there is a significant performance and concurrency trade-off for that space-efficiency gain. COMPRESSED tables are not recommended for production use in most situations, while DYNAMIC row format scales well in high-performance environments.

Supported Index Prefix Limits

The limit for indexing column values depends on the innodb_page_size value:

Page Size	Index Prefix Limit
16k 32k 16k	3072 bytes
8k	1536 bytes
4k	768 bytes

Using the DYNAMIC Row Format

The default row format is `DYNAMIC`, as long as the innodb_default_row_format system variable has not been modified. Therefore, in these versions, the easiest way to create an InnoDB table that uses the `DYNAMIC` row format is by **not** setting the ROW_FORMAT table option at all in a CREATE TABLE or ALTER TABLE statement.

It is recommended to set the innodb_strict_mode system variable to `ON` when using this row format.

For example:

```
SET SESSION innodb_strict_mode=ON;

SET GLOBAL innodb_default_row_format='dynamic';

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB;
```

Create an InnoDB Table with the Dynamic Row Format by Default

InnoDB uses the Dynamic row format for new InnoDB tables by default, because the innodb_default_row_format system variable is dynamic by default.

Let's create an InnoDB table after confirming that the default storage engine is InnoDB and that InnoDB's default row format is Dynamic:

1. Connect to the server using MariaDB Client:

```
$ mariadb --user=root
```

2. Confirm that the default storage engine is InnoDB by checking the default_storage_engine system variable using the SHOW SESSION VARIABLES statement:

```
SHOW SESSION VARIABLES
   LIKE 'default_storage_engine';
```

```
+------------------------+--------+
| Variable_name          | Value  |
+------------------------+--------+
| default_storage_engine | InnoDB |
+------------------------+--------+
```

3. Confirm that InnoDB's default row format is Dynamic by checking the innodb_default_row_format system variable using the SHOW GLOBAL VARIABLES statement:

```
SHOW GLOBAL VARIABLES
   LIKE 'innodb_default_row_format';
```

```
+---------------------------+---------+
| Variable_name             | Value   |
+---------------------------+---------+
| innodb_default_row_format | dynamic |
+---------------------------+---------+
```

4. If the database does not exist, then create the database for the table using the CREATE DATABASE statement:

```
CREATE DATABASE hq_sales;
```

5. Create the table using the CREATE TABLE statement:

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
);
```

6. Confirm that the table uses the Dynamic row format by querying the information_schema.INNODB_SYS_TABLES table:

```
SELECT NAME, ROW_FORMAT
FROM information_schema.INNODB_SYS_TABLES
WHERE NAME='hq_sales/invoices';
```

```
+------------------+------------+
| NAME             | ROW_FORMAT |
+------------------+------------+
| hq_sales/invoices | Dynamic    |
+------------------+------------+
```

Create an InnoDB Table with the Dynamic Row Format using `ROW_FORMAT`

An InnoDB table that uses the Dynamic row format can be created using the `ROW_FORMAT` table option.

Let's create an InnoDB table after confirming that the default storage engine is InnoDB and that InnoDB's default row format is not Dynamic:

1. Connect to the server using MariaDB Client:

```
$ mariadb --user=root
```

2. Confirm that the default storage engine is InnoDB by checking the default_storage_engine system variable using the SHOW SESSION VARIABLES statement:

```
SHOW SESSION VARIABLES
   LIKE 'default_storage_engine';
```

```
+------------------------+--------+
| Variable_name          | Value  |
+------------------------+--------+
| default_storage_engine | InnoDB |
+------------------------+--------+
```

3. Confirm that InnoDB's default row format is not Dynamic by checking the innodb_default_row_format system variable using the SHOW GLOBAL VARIABLES statement:

```
SHOW GLOBAL VARIABLES
   LIKE 'innodb_default_row_format';
```

```
+---------------------------+---------+
| Variable_name             | Value   |
+---------------------------+---------+
| innodb_default_row_format | compact |
+---------------------------+---------+
```

4. If the database does not exist, then create the database for the table using the CREATE DATABASE statement:

```
CREATE DATABASE hq_sales;
```

5. Create the table using the CREATE TABLE statement, and specify the Dynamic row format using the `ROW_FORMAT` table option:

```
CREATE TABLE hq_sales.invoices (
   invoice_id BIGINT UNSIGNED AUTO_INCREMENT NOT NULL,
   branch_id INT NOT NULL,
   customer_id INT,
   invoice_date DATETIME(6),
   invoice_total DECIMAL(13, 2),
   payment_method ENUM('NONE', 'CASH', 'WIRE_TRANSFER', 'CREDIT_CARD', 'GIFT_CARD'),
   PRIMARY KEY(invoice_id)
) ROW_FORMAT = DYNAMIC;
```

6. Confirm that the table uses the Dynamic row format by querying the information_schema.INNODB_SYS_TABLES table:

```
SELECT NAME, ROW_FORMAT
FROM information_schema.INNODB_SYS_TABLES
WHERE NAME='hq_sales/invoices';
```

```
+------------------+------------+
| NAME             | ROW_FORMAT |
+------------------+------------+
| hq_sales/invoices | Dynamic    |
+------------------+------------+
```

Convert InnoDB Tables to the Dynamic Row Format

If your database was physically upgraded from some older version of MariaDB Server or MySQL, then some of your tables may not be using the Dynamic row format. If you want to get the benefits of the Dynamic row format, then those tables will need to be converted to use it.

Let's convert some InnoDB tables to the Dynamic row format:

1. Connect to the server using MariaDB Client:

```
$ mariadb --user=root
```

2. Search for InnoDB tables that do not use the Dynamic row format by querying the information_schema.INNODB_SYS_TABLES table:

```
SELECT NAME, ROW_FORMAT
FROM information_schema.INNODB_SYS_TABLES
WHERE NAME NOT LIKE 'SYS_%'
AND ROW_FORMAT != 'Dynamic';
```

```
+------------------+------------+
| NAME             | ROW_FORMAT |
+------------------+------------+
| hq_sales/invoices | Compact    |
+------------------+------------+
```

3. Alter the table using the ALTER TABLE statement, and specify the Dynamic row format using the `ROW_FORMAT` table option:

```
ALTER TABLE hq_sales.invoices
   ROW_FORMAT = DYNAMIC;
```

4. Confirm that the table uses the Dynamic row format by querying the information_schema.INNODB_SYS_TABLES table again:

```
SELECT NAME, ROW_FORMAT
FROM information_schema.INNODB_SYS_TABLES
WHERE NAME='hq_sales/invoices';
```

```
+------------------+------------+
| NAME             | ROW_FORMAT |
+------------------+------------+
| hq_sales/invoices | Dynamic    |
+------------------+------------+
```

Index Prefixes with the DYNAMIC Row Format

The `DYNAMIC` row format supports index prefixes up to 3072 bytes. In earlier versions of MariaDB, the innodb_large_prefix system variable is used to configure the maximum index prefix length. In these versions, if innodb_large_prefix is set to `ON`, then the maximum prefix length is 3072 bytes, and if it is set to `OFF`, then the maximum prefix length is 767 bytes.

Overflow Pages with the DYNAMIC Row Format

All InnoDB row formats can store certain kinds of data in overflow pages. This allows for the maximum row size of an InnoDB table to be larger than the maximum amount of data that can be stored in the row's main data page. See Maximum Row Size for more information about the other factors that can contribute to the maximum row size for InnoDB tables.

In the `DYNAMIC` row format variable-length columns, such as columns using the VARBINARY, VARCHAR, BLOB and TEXT data types, can be completely stored in overflow pages.

InnoDB only considers using overflow pages if the table's row size is greater than half of innodb_page_size. If the row size is greater than this, then InnoDB chooses variable-length columns to be stored on overflow pages until the row size is less than half of innodb_page_size.

For BLOB and TEXT columns, only values longer than 40 bytes are considered for storage on overflow pages. For VARBINARY and VARCHAR columns, only values longer than 255 bytes are considered for storage on overflow pages. Bytes that are stored to track a value's length do not count towards these limits. These limits are only based on the length of the actual column's data.

These limits differ from the limits for the `COMPACT` row format, where the limit is 767 bytes for all types.

Fixed-length columns greater than 767 bytes are encoded as variable-length columns, so they can also be stored in overflow pages if the table's row size is greater than half of innodb_page_size. Even though a column using the CHAR data type can hold at most 255 characters, a CHAR column can still exceed 767 bytes in some cases. For example, a `char(255)` column can exceed 767 bytes if the character set is `utf8mb4`.

If a column is chosen to be stored on overflow pages, then the entire value of the column is stored on overflow pages, and only a 20-byte pointer to the column's first overflow page is stored on the main page. Each overflow page is the size of innodb_page_size. If a column is too large to be stored on a single overflow page, then it is stored on multiple overflow pages. Each overflow page contains part of the data and a 20-byte pointer to the next overflow page, if a next page exists.

This behavior differs from the behavior of the `COMPACT` row format, which always stores the column prefix on the main page. This allows tables using the `DYNAMIC` row format to contain a high number of columns using the VARBINARY, VARCHAR, BLOB and TEXT data types.

InnoDB REDUNDANT Row Format

The `REDUNDANT` row format is the original non-compacted row format.

The `REDUNDANT` row format was the only available row format before MySQL 5.0.3. In that release, this row format was retroactively named the `REDUNDANT` row format. In the same release, the `COMPACT` row format was introduced as the new default row format.

Using the `REDUNDANT` Row Format

- Redundant row format should not be used in modern versions of MariaDB Server.
- Redundant row format does not store large columns as efficiently as the Dynamic row format.
- Redundant row format limits indexing column values to 767 bytes, which is significant smaller than the Dynamic row format.

The easiest way to create an InnoDB table that uses the `REDUNDANT` row format is by setting the ROW_FORMAT table option to `REDUNDANT` in a CREATE TABLE or ALTER TABLE statement.

It is recommended to set the innodb_strict_mode system variable to `ON` when using this format.

The `REDUNDANT` row format is supported by both the `Antelope` and the `Barracuda` file formats, so tables with this row format can be created regardless of the value of the innodb_file_format system variable.

For example:

```
SET SESSION innodb_strict_mode=ON;

CREATE TABLE tab (
   id INT,
   str VARCHAR(50)
) ENGINE=InnoDB ROW_FORMAT=REDUNDANT;
```

Index Prefixes with the `REDUNDANT` Row Format

The `REDUNDANT` row format supports index prefixes up to 767 bytes.

Overflow Pages with the `REDUNDANT` Row Format

All InnoDB row formats can store certain kinds of data in overflow pages. This allows for the maximum row size of an InnoDB table to be larger than the maximum amount of data that can be stored in the row's main data page. See Maximum Row Size for more information about the other factors that can contribute to the maximum row size for InnoDB tables.

In the `REDUNDANT` row format variable-length columns, such as columns using the VARBINARY, VARCHAR, BLOB and TEXT data types, can be partially stored in overflow pages.

InnoDB only considers using overflow pages if the table's row size is greater than half of innodb_page_size. If the row size is greater than this, then InnoDB chooses variable-length columns to be stored on overflow pages until the row size is less than half of innodb_page_size.

For VARBINARY, VARCHAR, BLOB and TEXT columns, only values longer than 767 bytes are considered for storage on overflow pages. Bytes that are stored to track a value's length do not count towards this limit. This limit is only based on the length of the actual column's data.

Fixed-length columns greater than 767 bytes are encoded as variable-length columns, so they can also be stored in overflow pages if the table's row size is greater than half of innodb_page_size. Even though a column using the CHAR data type can hold at most 255 characters, a CHAR column can still exceed 767 bytes in some cases. For example, a `char(255)` column can exceed 767 bytes if the character set is `utf8mb4`.

If a column is chosen to be stored on overflow pages, then the first 767 bytes of the column's value and a 20-byte pointer to the column's first overflow page are stored on the main page. Each overflow page is the size of [innodb-system-variables#innodb_page_size|innodb_page_size]]. If a column is too large to be stored on a single overflow page, then it is stored on multiple overflow pages. Each overflow page contains part of the data and a 20-byte pointer to the next overflow page, if a next page exists.

Troubleshooting Row Size Too Large Errors with InnoDB

Overview

With InnoDB, users can see the following message as an error or warning:

```
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT or BLOB may help. In current row format, BLOB prefix of 0 bytes is stored
inline.
```

And they can also see the following message as an error or warning in the error log:

```
[Warning] InnoDB: Cannot add field col in table db1.tab because after adding it,
the row size is 8478 which is greater than maximum allowed size (8126) for a
record on index leaf page.
```

These messages indicate that the table definition allows rows that InnoDB row format can't store.

These messages are raised in the following cases:

- If InnoDB strict mode is enabled and if a DDL statement is executed that touches the table, such as CREATE TABLE or ALTER TABLE, InnoDB raises an error with the above message.
- If InnoDB strict mode is disabled and if a DDL statement is executed that touches the table, such as CREATE TABLE or ALTER TABLE, InnoDB raises a warning with the above message.
- Regardless of whether InnoDB strict mode is enabled, if a DML statement is executed that attempts to write a row that the table's InnoDB row format can't store, InnoDB raises an error with the above message.

Does the Problem Affect me?

The cause of the problem is described here. In very short, it affected old MariaDB versions (up to 10.2.26, 10.3.17, and 10.4.7). If you're on a newer version, the problem could yet still come up if the following applies:

- You created tables with a MariaDB version that has the problem.
- The tables weren't changed by any DML[14] statements in a newer MariaDB version since then.

If that's the case, you could still face the `Row size too large` error, particularly when issuing statements like ALTER TABLE or OPTIMIZE TABLE.

> **Note:**
>
> Take into account that the `Row size too large` error can come up for a good reason, for instance, when issuing DDL statements that actually exceed the row size.

> **Note:**
>
> For tables created in old MariaDB versions, an additional issue could come up: Tables were created whose row size wasn't calculated correctly. Creating those tables should have failed with the `Row size too large error`, but didn't.
>
> With such tables, you can get failures, both for DML (when inserted or updated data actually exceed the row size limit), and for DDL operations that should not affect the row size, like `TRUNCATE TABLE`, `CREATE TABLE LIKE`, or `OPTIMIZE TABLE`, or even dropping columns with `ALTER TABLE ... DROP COLUMN` which makes the row size shorter.

Example of the Problem

Here is an example of the problem:

```
SET GLOBAL innodb_default_row_format='dynamic';

SET SESSION innodb_strict_mode=ON;

CREATE OR REPLACE TABLE tab (
   col1 VARCHAR(40) NOT NULL,
   col2 VARCHAR(40) NOT NULL,
   col3 VARCHAR(40) NOT NULL,
   col4 VARCHAR(40) NOT NULL,
   col5 VARCHAR(40) NOT NULL,
   col6 VARCHAR(40) NOT NULL,
   col7 VARCHAR(40) NOT NULL,
   col8 VARCHAR(40) NOT NULL,
   col9 VARCHAR(40) NOT NULL,
   col10 VARCHAR(40) NOT NULL,
   col11 VARCHAR(40) NOT NULL,
   col12 VARCHAR(40) NOT NULL,
   col13 VARCHAR(40) NOT NULL,
   col14 VARCHAR(40) NOT NULL,
   col15 VARCHAR(40) NOT NULL,
   col16 VARCHAR(40) NOT NULL,
   col17 VARCHAR(40) NOT NULL,
   col18 VARCHAR(40) NOT NULL,
   col19 VARCHAR(40) NOT NULL,
   col20 VARCHAR(40) NOT NULL,
   col21 VARCHAR(40) NOT NULL,
   col22 VARCHAR(40) NOT NULL,
   col23 VARCHAR(40) NOT NULL,
   col24 VARCHAR(40) NOT NULL,
   col25 VARCHAR(40) NOT NULL,
   col26 VARCHAR(40) NOT NULL,
   col27 VARCHAR(40) NOT NULL,
   col28 VARCHAR(40) NOT NULL,
   col29 VARCHAR(40) NOT NULL,
   col30 VARCHAR(40) NOT NULL,
   col31 VARCHAR(40) NOT NULL,
   col32 VARCHAR(40) NOT NULL,
   col33 VARCHAR(40) NOT NULL,
   col34 VARCHAR(40) NOT NULL,
   col35 VARCHAR(40) NOT NULL,
   col36 VARCHAR(40) NOT NULL,
   col37 VARCHAR(40) NOT NULL,
   col38 VARCHAR(40) NOT NULL,
   col39 VARCHAR(40) NOT NULL,
   col40 VARCHAR(40) NOT NULL,
   col41 VARCHAR(40) NOT NULL,
   col42 VARCHAR(40) NOT NULL,
   col43 VARCHAR(40) NOT NULL,
   col44 VARCHAR(40) NOT NULL,
   col45 VARCHAR(40) NOT NULL,
   col46 VARCHAR(40) NOT NULL,
   col47 VARCHAR(40) NOT NULL,
   col48 VARCHAR(40) NOT NULL,
   col49 VARCHAR(40) NOT NULL,
   col50 VARCHAR(40) NOT NULL,
   col51 VARCHAR(40) NOT NULL,
   col52 VARCHAR(40) NOT NULL,
   col53 VARCHAR(40) NOT NULL,
   col54 VARCHAR(40) NOT NULL,
   col55 VARCHAR(40) NOT NULL,
   col56 VARCHAR(40) NOT NULL,
   col57 VARCHAR(40) NOT NULL,
   col58 VARCHAR(40) NOT NULL,
   col59 VARCHAR(40) NOT NULL,
   col60 VARCHAR(40) NOT NULL,
   col61 VARCHAR(40) NOT NULL,
   col62 VARCHAR(40) NOT NULL,
   col63 VARCHAR(40) NOT NULL,
```

```
    col64 VARCHAR(40) NOT NULL,
    col65 VARCHAR(40) NOT NULL,
    col66 VARCHAR(40) NOT NULL,
    col67 VARCHAR(40) NOT NULL,
    col68 VARCHAR(40) NOT NULL,
    col69 VARCHAR(40) NOT NULL,
    col70 VARCHAR(40) NOT NULL,
    col71 VARCHAR(40) NOT NULL,
    col72 VARCHAR(40) NOT NULL,
    col73 VARCHAR(40) NOT NULL,
    col74 VARCHAR(40) NOT NULL,
    col75 VARCHAR(40) NOT NULL,

```

```
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT or BLOB may help. In current row format, BLOB prefix of 0 bytes is stored inline.
```

Root Cause of the Problem

The root cause is that InnoDB has a maximum row size that is roughly equivalent to half of the value of the innodb_page_size system variable. See InnoDB Row Formats Overview: Maximum Row Size for more information.

The InnoDB row formats work around this limit by storing certain kinds of variable-length columns on overflow pages. However, different row formats can store different types of data on overflow pages. Some row formats can store more data in overflow pages than others. For example, the DYNAMIC and COMPRESSED row formats can store the most data in overflow pages. To learn how the various InnoDB row formats use overflow pages, see the following pages:

- InnoDB REDUNDANT Row Format: Overflow Pages with the REDUNDANT Row Format
- InnoDB COMPACT Row Format: Overflow Pages with the COMPACT Row Format
- InnoDB DYNAMIC Row Format: Overflow Pages with the DYNAMIC Row Format
- InnoDB COMPRESSED Row Format: Overflow Pages with the COMPRESSED Row Format

Checking Existing Tables for the Problem

InnoDB does not currently have an easy way to check all existing tables to determine which tables have this problem. See MDEV-20400 for more information.

One method to check a single existing table for this problem is to enable InnoDB strict mode, and then try to create a duplicate of the table with CREATE TABLE … LIKE. If the table has this problem, then the operation fails:

```
SET SESSION innodb_strict_mode=ON;

CREATE TABLE tab_dup LIKE tab;
ERROR 1118 (42000): Row size too large (> 8126). Changing some columns to
TEXT or BLOB may help. In current row format, BLOB prefix of 0 bytes is stored inline.
```

Finding All Tables That Currently Have the Problem

The following shell script will read through a MariaDB server to identify every table that has a row size definition that is too large for its row format and the server's page size. It runs on most common distributions of Linux.

To run the script, copy the code below to a shell-script named `rowsize.sh`, make it executable with the command `chmod 755 ./rowsize.sh`, and invoke it with the following parameters:

```
./rowsize.sh host user password
```

When the script runs, it displays the name of the temporary database it creates, so that if the script is interrupted before cleaning up, the database can be easily identified and removed manually.

As the script runs it will output one line reporting the database and tablename for each table it finds that has the oversize row problem. If it finds none, it will print the following message: "No tables with rows size too big found."

In either case, the script prints one final line to announce when it's done: `./rowsize.sh done.`

```
#!/bin/bash

[ -z "$3" ] && echo "Usage: $0 host user password" >&2 && exit 1

dt="tmp_$RANDOM$RANDOM"

mysql -h $1 -u $2 -p$3 -ABNe "create database $dt;"
[ $? -ne 0 ] && echo "Error: $0 terminating" >&2 exit 1

echo
echo "Created temporary database ${dt} on host $1"
echo

c=0
for d in $(mysql -h $1 -u $2 -p$3 -ABNe "show databases;" | egrep -iv
"information_schema|mysql|performance_schema|$dt")
do
    for t in $(mysql -h $1 -u $2 -p$3 -ABNe "show tables;" $d)
    do
        tc=$(mysql -h $1 -u $2 -p$3 -ABNe "show create table $t\\G" $d | egrep -iv "^\*|^$t")

        echo $tc | grep -iq "ROW_FORMAT"
        if [ $? -ne 0 ]
        then
            tf=$(mysql -h $1 -u $2 -p$3 -ABNe "select row_format from
information_schema.innodb_sys_tables where name = '${d}/${t}';")
            tc="$tc ROW_FORMAT=$tf"
        fi

        ef="/tmp/e$RANDOM$RANDOM"
        mysql -h $1 -u $2 -p$3 -ABNe "set innodb_strict_mode=1; set foreign_key_checks=0; ${tc};" $dt
>/dev/null  2>$ef
        [ $? -ne 0 ] && cat $ef | grep -q "Row size too large" && echo "${d}.${t}" && let c++ || mysql -h
$1 -u $2 -p$3 -ABNe "drop table if exists ${t};" $dt
        rm -f $ef
    done
done
mysql -h $1 -u $2 -p$3 -ABNe "set innodb_strict_mode=1; drop database $dt;"
[ $c -eq 0 ] && echo "No tables with rows size too large found." || echo && echo "$c tables found with
row size too large."
echo
echo "$0 done."
```

Solving the Problem

There are several potential solutions available to solve this problem.

Converting the Table to the DYNAMIC Row Format

If the table is using either the REDUNDANT or the COMPACT row format, then one potential solution to this problem is to convert the table to use the DYNAMIC row format instead.

If your tables were originally created on an older version of MariaDB or MySQL, then your table may be using one of InnoDB's older row formats:

- In MariaDB 10.1 and before, and in MySQL 5.6 and before, the COMPACT row format was the default row format.
- In MySQL 4.1 and before, the REDUNDANT row format was the default row format.

The DYNAMIC row format can store more data on overflow pages than these older row formats, so this row format may actually be able to store the table's data safely. See InnoDB DYNAMIC Row Format: Overflow Pages with the DYNAMIC Row Format for more information.

Therefore, a potential solution to the *Row size too large* error is to convert the table to use the DYNAMIC row format:

```
ALTER TABLE tab ROW_FORMAT=DYNAMIC;
```

You can use the INNODB_SYS_TABLES table in the information_schema database to find all tables that use the REDUNDANT or the COMPACT row formats. This is helpful if you would like to convert all of your tables that you still use the older row formats to the DYNAMIC row format. For example, the following query can find those tables, while excluding InnoDB's internal system tables:

```
SELECT NAME, ROW_FORMAT
FROM information_schema.INNODB_SYS_TABLES
WHERE ROW_FORMAT IN('Redundant', 'Compact')
AND NAME NOT IN('SYS_DATAFILES', 'SYS_FOREIGN', 'SYS_FOREIGN_COLS', 'SYS_TABLESPACES', 'SYS_VIRTUAL',
'SYS_ZIP_DICT', 'SYS_ZIP_DICT_COLS');
```

In MariaDB 10.2 and later, the DYNAMIC row format is the default row format. If your tables were originally created on one of these newer versions, then they may already be using this row format. In that case, you may need to try the next solution.

Fitting More Columns on Overflow Pages

If the table is already using the DYNAMIC row format, then another potential solution to this problem is to change the table schema, so that the row format can store more columns on overflow pages.

In order for InnoDB to store some variable-length columns on overflow pages, the length of those columns may need to be increased.

Therefore, a counter-intuitive solution to the *Row size too large* error in a lot of cases is actually to **increase** the length of some variable-length columns, so that InnoDB's row format can store them on overflow pages.

Some possible ways to change the table schema are listed below.

Converting Some Columns to `BLOB` or `TEXT`

For BLOB and TEXT columns, the DYNAMIC row format can store these columns on overflow pages. See InnoDB DYNAMIC Row Format: Overflow Pages with the DYNAMIC Row Format for more information.

Therefore, a potential solution to the *Row size too large* error is to convert some columns to the BLOB or TEXT data types.

Increasing the Length of `VARBINARY` Columns

For VARBINARY columns, the DYNAMIC row format can only store these columns on overflow pages if the maximum length of the column is 256 bytes or longer. See InnoDB DYNAMIC Row Format: Overflow Pages with the DYNAMIC Row Format for more information.

Therefore, a potential solution to the *Row size too large* error is to ensure that all VARBINARY columns are at least as long as `varbinary(256)`.

Increasing the Length of `VARCHAR` Columns

For VARCHAR columns, the DYNAMIC row format can only store these columns on overflow pages if the maximum length of the column is 256 bytes or longer. See InnoDB DYNAMIC Row Format: Overflow Pages with the DYNAMIC Row Format for more information.

The original table schema shown earlier on this page causes the *Row size too large* error, because all of the table's VARCHAR columns are smaller than 256 bytes, which means that they have to be stored on the row's main data

page.

Therefore, a potential solution to the *Row size too large* error is to ensure that all VARCHAR columns are at least as long as 256 bytes. The number of characters required to reach the 256 byte limit depends on the character set used by the column.

For example, when using InnoDB's DYNAMIC row format and a default character set of latin1 (which requires up to 1 byte per character), the 256 byte limit means that a VARCHAR column will only be stored on overflow pages if it is at least as large as a `varchar(256)`:

```
SET GLOBAL innodb_default_row_format='dynamic';
SET SESSION innodb_strict_mode=ON;
CREATE OR REPLACE TABLE tab (
   col1 VARCHAR(256) NOT NULL,
   col2 VARCHAR(256) NOT NULL,

   col155 VARCHAR(256) NOT NULL,
   col156 VARCHAR(256) NOT NULL,
   col157 VARCHAR(256) NOT NULL,
   col158 VARCHAR(256) NOT NULL,
   col159 VARCHAR(256) NOT NULL,
   col160 VARCHAR(256) NOT NULL,
   col161 VARCHAR(256) NOT NULL,
   col162 VARCHAR(256) NOT NULL,
   col163 VARCHAR(256) NOT NULL,
   col164 VARCHAR(256) NOT NULL,
   col165 VARCHAR(256) NOT NULL,
   col166 VARCHAR(256) NOT NULL,
   col167 VARCHAR(256) NOT NULL,
   col168 VARCHAR(256) NOT NULL,
   col169 VARCHAR(256) NOT NULL,
   col170 VARCHAR(256) NOT NULL,
   col171 VARCHAR(256) NOT NULL,
   col172 VARCHAR(256) NOT NULL,
   col173 VARCHAR(256) NOT NULL,
   col174 VARCHAR(256) NOT NULL,
   col175 VARCHAR(256) NOT NULL,
   col176 VARCHAR(256) NOT NULL,
   col177 VARCHAR(256) NOT NULL,
   col178 VARCHAR(256) NOT NULL,
   col179 VARCHAR(256) NOT NULL,
   col180 VARCHAR(256) NOT NULL,
   col181 VARCHAR(256) NOT NULL,
   col182 VARCHAR(256) NOT NULL,
   col183 VARCHAR(256) NOT NULL,
   col184 VARCHAR(256) NOT NULL,
   col185 VARCHAR(256) NOT NULL,
   col186 VARCHAR(256) NOT NULL,
   col187 VARCHAR(256) NOT NULL,
   col188 VARCHAR(256) NOT NULL,
   col189 VARCHAR(256) NOT NULL,
   col190 VARCHAR(256) NOT NULL,
   col191 VARCHAR(256) NOT NULL,
   col192 VARCHAR(256) NOT NULL,
   col193 VARCHAR(256) NOT NULL,
   col194 VARCHAR(256) NOT NULL,
   col195 VARCHAR(256) NOT NULL,
   col196 VARCHAR(256) NOT NULL,
   col197 VARCHAR(256) NOT NULL,
   col198 VARCHAR(256) NOT NULL,
   PRIMARY KEY (col1)
) ENGINE=InnoDB DEFAULT CHARSET=latin1;
```

And when using InnoDB's DYNAMIC row format and a default character set of utf8 (which requires up to 3 bytes per character), the 256 byte limit means that a VARCHAR column will only be stored on overflow pages if it is at least as large as a `varchar(86)`:

```
SET GLOBAL innodb_default_row_format='dynamic';
SET SESSION innodb_strict_mode=ON;
CREATE OR REPLACE TABLE tab (
   col1 VARCHAR(86) NOT NULL,
   col2 VARCHAR(86) NOT NULL,
   col3 VARCHAR(86) NOT NULL,
   col4 VARCHAR(86) NOT NULL,
   col5 VARCHAR(86) NOT NULL,
   col6 VARCHAR(86) NOT NULL,
   col7 VARCHAR(86) NOT NULL,
   col8 VARCHAR(86) NOT NULL,
   col9 VARCHAR(86) NOT NULL,
   col10 VARCHAR(86) NOT NULL,
   col11 VARCHAR(86) NOT NULL,
   col12 VARCHAR(86) NOT NULL,

   col197 VARCHAR(86) NOT NULL,
   col198 VARCHAR(86) NOT NULL,
   PRIMARY KEY (col1)
) ENGINE=InnoDB DEFAULT CHARSET=utf8;
```

And when using InnoDB's DYNAMIC row format and a default character set of utf8mb4 (which requires up to 4 bytes per character), the 256 byte limit means that a VARCHAR column will only be stored on overflow pages if it is at least as large as a `varchar(64)`:

```
SET GLOBAL innodb_default_row_format='dynamic';
SET SESSION innodb_strict_mode=ON;
CREATE OR REPLACE TABLE tab (
   col1 VARCHAR(64) NOT NULL,
   col2 VARCHAR(64) NOT NULL,
   col3 VARCHAR(64) NOT NULL,
   col4 VARCHAR(64) NOT NULL,
   col5 VARCHAR(64) NOT NULL,
   col6 VARCHAR(64) NOT NULL,

```

Working Around the Problem

There are a few ways to work around this problem.

If you would like a solution for the problem instead of just working around it, then see the solutions mentioned in the previous section.

Refactoring the Table into Multiple Tables

A *safe* workaround is to refactor the single wide table, so that its columns are spread among multiple tables.

This workaround can even work if your table is so wide that the previous solutions have failed to solve them problem for your table.

Refactoring Some Columns into JSON

A *safe* workaround is to refactor some of the columns into a JSON document.

The JSON document can be queried and manipulated using MariaDB's JSON functions.

The JSON document can be stored in a column that uses one of the following data types:

- TEXT: The maximum size of a TEXT column is 64 KB.
- MEDIUMTEXT: The maximum size of a MEDIUMTEXT column is 16 MB.
- LONGTEXT: The maximum size of a LONGTEXT column is 4 GB.
- JSON: This is just an alias for the LONGTEXT data type.

This workaround can even work if your table is so wide that the previous solutions have failed to solve them problem for your table.

Disabling InnoDB Strict Mode

An *unsafe* workaround is to disable InnoDB strict mode. InnoDB strict mode can be disabled by setting the innodb_strict_mode system variable to `OFF`.

For example, even though the following table schema is too large for most InnoDB row formats to store, it can still be created when InnoDB strict mode is disabled:

```
SET GLOBAL innodb_default_row_format='dynamic';
SET SESSION innodb_strict_mode=OFF;
CREATE OR REPLACE TABLE tab (
   col1 VARCHAR(40) NOT NULL,
   col2 VARCHAR(40) NOT NULL,
   col3 VARCHAR(40) NOT NULL,
   col4 VARCHAR(40) NOT NULL,
   col5 VARCHAR(40) NOT NULL,
   col6 VARCHAR(40) NOT NULL,
   col7 VARCHAR(40) NOT NULL,
   col8 VARCHAR(40) NOT NULL,
   col9 VARCHAR(40) NOT NULL,
   col10 VARCHAR(40) NOT NULL,
   col11 VARCHAR(40) NOT NULL,
   col12 VARCHAR(40) NOT NULL,
   col13 VARCHAR(40) NOT NULL,
   col14 VARCHAR(40) NOT NULL,
   col15 VARCHAR(40) NOT NULL,
   col16 VARCHAR(40) NOT NULL,
   col17 VARCHAR(40) NOT NULL,
   col18 VARCHAR(40) NOT NULL,
   col19 VARCHAR(40) NOT NULL,
   col20 VARCHAR(40) NOT NULL,
   col21 VARCHAR(40) NOT NULL,

   col191 VARCHAR(40) NOT NULL,
   col192 VARCHAR(40) NOT NULL,
   col193 VARCHAR(40) NOT NULL,
   col194 VARCHAR(40) NOT NULL,
   col195 VARCHAR(40) NOT NULL,
   col196 VARCHAR(40) NOT NULL,
   col197 VARCHAR(40) NOT NULL,
   col198 VARCHAR(40) NOT NULL,
   PRIMARY KEY (col1)
) ENGINE=InnoDB DEFAULT CHARSET=utf8mb4;
```

But as mentioned above, if InnoDB strict mode is **disabled** and if a DDL statement is executed, then InnoDB will still raise a **warning** with this message. The SHOW WARNINGS statement can be used to view the warning:

```
SHOW WARNINGS;
+---------+------+-----------------------------------------------------------------------------------------------
-----------------------------------------------------+
| Level | Code | Message |
+---------+------+-----------------------------------------------------------------------------------------------
-----------------------------------------------------+
| Warning | 139 | Row size too large (> 8126). Changing some columns to TEXT or BLOB may help. In current
row format, BLOB prefix of 0 bytes is stored inline. |
+---------+------+-----------------------------------------------------------------------------------------------
-----------------------------------------------------+
1 row in set (0.000 sec)
```

As mentioned above, even though InnoDB is allowing the table to be created, there is still an opportunity for errors. Regardless of whether InnoDB strict mode is enabled, if a DML statement is executed that attempts to write a row that the table's InnoDB row format can't store, then InnoDB will raise an **error** with this message. This creates a somewhat *unsafe* situation, because it means that the application has the chance to encounter an additional error while executing DML.

InnoDB File-Per-Table Tablespaces

When you create a table using the InnoDB storage engine, data written to that table is stored on the file system in a data file called a tablespace. Tablespace files contain both the data and indexes.

When innodb_file_per_table=ON is set, InnoDB uses one tablespace file per InnoDB table. These tablespace files have the `.ibd` extension. When innodb_file_per_table=OFF is set, InnoDB stores all tables in the InnoDB system tablespace.

InnoDB versions in MySQL 5.7 and above also support an additional type of tablespace called general tablespaces that are created with CREATE TABLESPACE. However, InnoDB versions in MariaDB Server do not support general tablespaces or CREATE TABLESPACE.

File-Per-Table Tablespace Locations

By default, InnoDB's file-per-table tablespaces are created in the system's data directory, which is defined by the datadir system variable. The system variable innodb_data_home_dir will not change the location of file-per-table tablespaces.

In the event that you have a specific tablespace that you need stored in a dedicated path, you can set the location using the DATA DIRECTORY table option when you create the table.

For instance,

```
CREATE TABLE test.t1 (
   id INT PRIMARY KEY AUTO_INCREMENT,
   name VARCHAR(50)
) ENGINE=InnoDB
DATA DIRECTORY = "/data/contact";
```

MariaDB then creates a database directory on the configured path and the file-per-table tablespace are created inside that directory. On Unix-like operating systems, you can see the file using the ls command:

```
# ls -al /data/contact/test
drwxrwx--- 2 mysql mysql  4096 Dec 8 18:46 .
drwxr-xr-x 3 mysql mysql  4096 Dec 8 18:46 ..
-rw-rw---- 1 mysql mysql 98304 Dec 8 20:41 t1.ibd
```

Note, the system user that runs the MariaDB Server process (which is usually `mysql`) must have write permissions on the given path.

Copying Transportable Tablespaces

InnoDB's file-per-table tablespaces are transportable, which means that you can copy a file-per-table tablespace from one MariaDB Server to another server. You may find this useful in cases where you need to transport full tables between servers and don't want to use backup tools like mariadb-backup or mariadb-dump. In fact, this process can even be used with mariadb-backup in some cases, such as when restoring partial backups or when restoring individual tables or partitions from a backup.

Copying Transportable Tablespaces for Non-partitioned Tables

You can copy the transportable tablespace of a non-partitioned table from one server to another by exporting the tablespace file from the original server, and then importing the tablespace file into the new server.

MariaDB starting with 11.2.1

The workflow is simplified starting from MariaDB 11.2.1. On the source server, simply do:

```
FLUSH TABLES t1 FOR EXPORT;
# scp /data/contacts/test/t1.ibd target-server.com:/var/lib/mysql/test/
# scp /data/contacts/test/t1.cfg target-server.com:/var/lib/mysql/test/
# scp /data/contacts/test/t1.frm target-server.com:/var/lib/mysql/test/
UNLOCK TABLES;
```

On the destination server, simply do:

```
ALTER TABLE t1 IMPORT TABLESPACE;
```

Exporting Transportable Tablespaces for Non-partitioned Tables

You can export a non-partitioned table by locking the table and copying the table's `.ibd` and `.cfg` files from the relevant tablespace location for the table to a backup location. For example, the process would go like this:

- First, use the FLUSH TABLES … FOR EXPORT statement on the target table:

```
FLUSH TABLES test.t1 FOR EXPORT;
```

This forces the server to close the table and provides your connection with a read lock on the table.

- Then, while your connection still holds the lock on the table, copy the tablespace file and the metadata file to a safe directory:

```
# cp /data/contacts/test/t1.ibd /data/saved-tablespaces/
# cp /data/contacts/test/t1.cfg /data/saved-tablespaces/
```

- Then, once you've copied the files, you can release the lock with UNLOCK TABLES:

```
UNLOCK TABLES;
```

Importing Transportable Tablespaces for Non-partitioned Tables

You can import a non-partitioned table by discarding the table's original tablespace, copying the table's `.ibd` and `.cfg` files from the backup location to the relevant tablespace location for the table, and then telling the server to import the tablespace.

For example, the process would go like this:

- First, on the destination server, you need to create a copy of the table. Use the same CREATE TABLE statement that was used to create the table on the original server.

```
CREATE TABLE test.t1 (
   id INT PRIMARY KEY AUTO_INCREMENT,
   name VARCHAR(50)
) ENGINE=InnoDB;
```

- Then, use ALTER TABLE … DISCARD TABLESPACE to discard the new table's tablespace:

```
ALTER TABLE test.t1 DISCARD TABLESPACE;
```

- Then, copy the `.ibd` and `.cfg` files from the original server to the relevant directory on the target MariaDB Server.

```
# scp /data/tablespaces/t1.ibd target-server.com:/var/lib/mysql/test/
# scp /data/tablespaces/t1.cfg target-server.com:/var/lib/mysql/test/
```

File-per-table tablespaces can be imported with just the `.ibd` file in many cases. If you do not have the tablespace's `.cfg` file for whatever reason, then it is usually worth trying to import the tablespace with just the `.ibd` file.

- Then, once the files are in the proper directory on the target server, use ALTER TABLE … IMPORT TABLESPACE to import the new table's tablespace:

```
ALTER TABLE test.t1 IMPORT TABLESPACE;
```

Copying Transportable Tablespaces for Partitioned Tables

Currently, MariaDB does not directly support the transport of tablespaces from partitioned tables. See MDEV-10568 for more information about that. It is still possible to transport partitioned tables if we use a workaround. You can copy the transportable tablespaces of a partitioned table from one server to another by exporting the tablespace file of each partition from the original server, and then importing the tablespace file of each partition into the new server.

Exporting Transportable Tablespaces for Partitioned Tables

You can export a partitioned table by locking the table and copying the `.ibd` and `.cfg` files of each partition from the relevant tablespace location for the partition to a backup location. For example, the process would go like this:

- First, let's create a test table with some data on the original server:

```
CREATE TABLE test.t2 (
   employee_id INT,
   name VARCHAR(50)
) ENGINE=InnoDB
PARTITION BY RANGE (employee_id) (
   PARTITION p0 VALUES LESS THAN (6),
   PARTITION p1 VALUES LESS THAN (11),
   PARTITION p2 VALUES LESS THAN (16),
   PARTITION p3 VALUES LESS THAN MAXVALUE
);

INSERT INTO test.t2 (name, employee_id) VALUES
   ('Geoff Montee', 1),
   ('Chris Calendar', 6),
   ('Kyle Joiner', 11),
   ('Will Fong', 16);
```

- Then, we need to export the partitioned tablespace from the original server, which follows the same process as exporting non-partitioned tablespaces. That means that we need to use the FLUSH TABLES … FOR EXPORT statement on the target table:

```
FLUSH TABLES test.t2 FOR EXPORT;
```

This forces the server to close the table and provides your connection with a read lock on the table.

- Then, if we grep the database directory in the data directory for the newly created `t2` table, we can see a number of `.ibd` and `.cfg` files for the table:

```
# ls -l /var/lib/mysql/test/ | grep t2
total 428
-rw-rw---- 1 mysql mysql 827 Dec 5 16:08 t2.frm
-rw-rw---- 1 mysql mysql 48 Dec 5 16:08 t2.par
-rw-rw---- 1 mysql mysql 579 Dec 5 18:47 t2#P#p0.cfg
-rw-r----- 1 mysql mysql 98304 Dec 5 16:43 t2#P#p0.ibd
-rw-rw---- 1 mysql mysql 579 Dec 5 18:47 t2#P#p1.cfg
-rw-rw---- 1 mysql mysql 98304 Dec 5 16:08 t2#P#p1.ibd
-rw-rw---- 1 mysql mysql 579 Dec 5 18:47 t2#P#p2.cfg
-rw-rw---- 1 mysql mysql 98304 Dec 5 16:08 t2#P#p2.ibd
-rw-rw---- 1 mysql mysql 579 Dec 5 18:47 t2#P#p3.cfg
-rw-rw---- 1 mysql mysql 98304 Dec 5 16:08 t2#P#p3.ibd
```

- Then, while our connection still holds the lock on the table, we need to copy the tablespace files and the metadata files to a safe directory:

```
$ mkdir /tmp/backup
$ sudo cp /var/lib/mysql/test/t2*.ibd /tmp/backup
$ sudo cp /var/lib/mysql/test/t2*.cfg /tmp/backup
```

- Then, once we've copied the files, we can release the lock with UNLOCK TABLES:

```
UNLOCK TABLES;
```

Importing Transportable Tablespaces for Partitioned Tables

You can import a partitioned table by creating a placeholder table, discarding the placeholder table's original tablespace, copying the partition's `.ibd` and `.cfg` files from the backup location to the relevant tablespace location for the placeholder table, and then telling the server to import the tablespace. At that point, the server can exchange the tablespace for the placeholder table with the one for the partition. For example, the process would go like this:

- First, we need to copy the saved tablespace files from the original server to the target server:

```
$ scp /tmp/backup/t2* user@target-host:/tmp/backup
```

- Then, we need to import the partitioned tablespaces onto the target server. The import process for partitioned tables is more complicated than the import process for non-partitioned tables. To start with, if it doesn't already exist, then we need to create a partitioned table on the target server that matches the partitioned table on the original server:

```
CREATE TABLE test.t2 (
   employee_id INT,
   name VARCHAR(50)
) ENGINE=InnoDB
PARTITION BY RANGE (employee_id) (
   PARTITION p0 VALUES LESS THAN (6),
   PARTITION p1 VALUES LESS THAN (11),
   PARTITION p2 VALUES LESS THAN (16),
   PARTITION p3 VALUES LESS THAN MAXVALUE
);
```

- Then, using this table as a model, we need to create a placeholder of this table with the same structure that does not use partitioning. This can be done with a CREATE TABLE… AS SELECT statement:

```
CREATE TABLE test.t2_placeholder LIKE test.t2;
ALTER TABLE test.t2_placeholder REMOVE PARTITIONING;
```

This statement will create a new table called `t2_placeholder` that has the same schema structure as `t2`, but it does not use partitioning and it contains no rows.

For Each Partition

From this point forward, the rest of our steps need to happen for each individual partition. For each partition, we need to do the following process:

- First, we need to use ALTER TABLE … DISCARD TABLESPACE to discard the placeholder table's tablespace:

```
ALTER TABLE test.t2_placeholder DISCARD TABLESPACE;
```

- Then, copy the `.ibd` and `.cfg` files for the next partition to the relevant directory for the `t2_placeholder` table on the target MariaDB Server:

```
# cp /tmp/backup/t2#P#p0.cfg /var/lib/mysql/test/t2_placeholder.cfg
# cp /tmp/backup/t2#P#p0.ibd /var/lib/mysql/test/t2_placeholder.ibd
# chown mysql:mysql /var/lib/mysql/test/t2_placeholder*
```

File-per-table tablespaces can be imported with just the `.ibd` file in many cases. If you do not have the tablepace's `.cfg` file for whatever reason, then it is usually worth trying to import the tablespace with just the `.ibd` file.

- Then, once the files are in the proper directory on the target server, we need to use ALTER TABLE … IMPORT TABLESPACE to import the new table's tablespace:

```
ALTER TABLE test.t2_placeholder IMPORT TABLESPACE;
```

The placeholder table now contains data from the `p0` partition on the source server.

```
SELECT * FROM test.t2_placeholder;

+-------------+--------------+
| employee_id | name         |
+-------------+--------------+
|           1 | Geoff Montee |
+-------------+--------------+
```

- Then, it's time to transfer the partition from the placeholder to the target table. This can be done with an ALTER TABLE… EXCHANGE PARTITION statement:

```
ALTER TABLE test.t2 EXCHANGE PARTITION p0 WITH TABLE test.t2_placeholder;
```

The target table now contains the first partition from the source table.

```
SELECT * FROM test.t2;

+-------------+--------------+
| employee_id | name         |
+-------------+--------------+
|           1 | Geoff Montee |
+-------------+--------------+
```

- Repeat this procedure for each partition you want to import. For each partition, we need to discard the placeholder table's tablespace, and then import the partitioned table's tablespace into the placeholder table, and then exchange the tablespaces between the placeholder table and the partition of our target table.

When this process is complete for all partitions, the target table will contain the imported data:

```
SELECT * FROM test.t2;

+-------------+----------------+
| employee_id | name           |
+-------------+----------------+
|           1 | Geoff Montee   |
|           6 | Chris Calendar |
|          11 | Kyle Joiner    |
|          16 | Will Fong      |
+-------------+----------------+
```

- Then, we can remove the placeholder table from the database:

```
DROP TABLE test.t2_placeholder;
```

Known Problems with Copying Transportable Tablespaces

Differing Storage Formats for Temporal Columns

MariaDB 10.1.2 added the mysql56_temporal_format system variable, which enables a new MySQL 5.6-compatible storage format for the TIME, DATETIME and TIMESTAMP data types.

If a file-per-tablespace file contains columns that use one or more of these temporal data types and if the tablespace file's original table was created with a certain storage format for these columns, then the tablespace file can only be imported into tables that were also created with the same storage format for these columns as the original table. Otherwise, you will see errors like the following:

```
ALTER TABLE dt_test IMPORT TABLESPACE;
ERROR 1808 (HY000): Schema mismatch (Column dt precise type mismatch.)
```

See MDEV-15225 for more information.

See the pages for the TIME, DATETIME and TIMESTAMP data types to determine how to update the storage format for temporal columns in tables that were created before MariaDB 10.1.2 or that were created with mysql56_temporal_format=OFF.

Differing ROW_FORMAT Values

InnoDB file-per-table tablespaces can use different row formats. A specific row format can be specified when creating a table either by setting the ROW_FORMAT table option or by the setting the innodb_default_row_format system variable. See Setting a Table's Row Format for more information on how to set an InnoDB table's row format.

If a file-per-tablespace file was created with a certain row format, then the tablespace file can only be imported into tables that were created with the same row format as the original table. Otherwise, you will see errors like the following:

```
ALTER TABLE t0 IMPORT TABLESPACE;
ERROR 1808 (HY000): Schema mismatch (Expected FSP_SPACE_FLAGS=0x21, .ibd file contains 0x0.)
```

The error message is a bit more descriptive in MariaDB 10.2.17 and later:

```
ALTER TABLE t0 IMPORT TABLESPACE;
ERROR 1808 (HY000): Schema mismatch (Table flags don't match, server table has 0x1 and the meta-data file
has 0x0; .cfg file uses ROW_FORMAT=REDUNDANT)
```

Be sure to check a tablespace's row format before moving it from one server to another. Keep in mind that the default row format can change between major versions of MySQL or MariaDB. See Checking a Table's Row Format for information on how to check an InnoDB table's row format.

See MDEV-15049 and MDEV-16851 for more information.

Foreign Key Constraints

DISCARD on a table with foreign key constraints is only possible after disabling foreign_key_checks:

```
SET SESSION foreign_key_checks=0;
ALTER TABLE t0 DISCARD TABLESPACE;
```

IMPORT on the other hand does not enforce foreign key constraints. So when importing tablespaces, referential integrity can only be guaranteed to import all tables bound by foreign key constraint at the same time, from an EXPORT of those tables taken with the same transactional state.

Tablespace Encryption

MariaDB supports data-at-rest encryption for the InnoDB storage engine. When enabled, the Server encrypts data before writing it to the tablespace and decrypts reads from the tablespace before returning result-sets. This means that a malicious user attempting to exfiltrate sensitive data won't be able to import the tablespace onto a different server as shown above without the encryption key.

For more information on data encryption, see Encrypting Data for InnoDB.

InnoDB System Tablespaces

When InnoDB needs to store general information relating to the system as a whole, rather than a specific table, the specific file it writes to is the system tablespace. By default, this is the `ibdata1` file located in the data directory, (as defined by either the datadir or innodb_data_home_dir system variables). InnoDB uses the system tablespace to store the data dictionary, change buffer, and undo logs.

You can define the system tablespace filename or filenames, size and other options by setting the innodb_data_file_path system variable. This system variable can be specified as a command-line argument to mariadbd or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_data_file_path=ibdata1:50M:autoextend
```

This system variable defaults to the file `ibdata1`, and it defaults to a minimum size of `12M`, and it defaults with the `autoextend` attribute enabled.

Changing Sizes

InnoDB defaults to allocating 12M to the `ibdata1` file for the system tablespace. While this is sufficient for most use cases, it may not be for all. You may find after using MariaDB for a while that the allocation is too small for the system tablespace or it grows too large for your disk. Fortunately, you can adjust this size as need later.

Increasing the Size

When setting the innodb_data_file_path system variable, you can define a size for each file given. In cases where you need a larger system tablespace, add the `autoextend` option to the last value.

```
[mariadb]
...
innodb_data_file_path=ibdata1:12M;ibdata2:50M:autoextend
```

Under this configuration, when the last system tablespace grows beyond the size allocation, InnoDB increases the size of the file by increments. To control the allocation increment, set the innodb_autoextend_increment system variable.

Decreasing the Size

MariaDB starting with 11.2

From MariaDB 11.2.0, when MariaDB starts up, unused InnoDB tablespace can be reclaimed, reducing the file size (MDEV-14795). This is disabled by default and is enabled by adding the `:autoshrink` attribute to the innodb_data_file_path system variable, e.g.:

```
[mariadb]
...
innodb_data_file_path=ibdata1:12M;ibdata2:50M:autoextend:autoshrink
```

Alternatively, starting with MariaDB 11.2.3, the shrinking can be set to happen during a slow shutdown (e.g. after `SET GLOBAL innodb_fast_shutdown=0`) (MDEV-32452).
Technically, how this works is:

1. Find the last used extent in the system tablespace by iterating through the BITMAP in the extent descriptor page.
2. Check whether the tablespace is being used within fixed size, and if the last used extent is less than the fixed size, then set the desired target size to fixed size.
3. Flush all pages belonging to the system tablespace in flush list.

4. Truncate the truncated pages from FSP_FREE and FSP_FREE_FRAG list.
5. Reset the bitmap in descriptor pages for the truncated pages.
6. Update the FSP_SIZE and FSP_FREE_LIMIT in header page.
7. In case of multiple files, calculate the truncated last file size and do the truncation in last file.

MariaDB until 11.2.0

In cases where the InnoDB system tablespace has grown too large, before MariaDB 11.2, the process to reduce it in size is a little more complicated than increasing the size. MariaDB does not allow you to remove data from the tablespace file itself. Instead you need to delete the tablespace files themselves, then restore the database from backups.
The backup utility mariadb-dump produces backup files containing the SQL statements needed to recreate the database. As a result, it restores a database with the bare minimum data rather than any additional information that might have built up in the tablespace file.
Use mariadb-dump to backup all of your InnoDB database tables, including the system tables in the `mysql` database that use InnoDB. You can find out what they are using the Information Schema.

```
SELECT TABLE_NAME FROM information_schema.TABLES
WHERE TABLE_SCHEMA = 'mysql' AND ENGINE = 'InnoDB';
```

If you only use InnoDB, you may find it easier to back up all databases and tables.

```
$ mariadb-dump -u root -p --all-databases > full-backup.sql
```

Then stop the MariaDB Server and remove the InnoDB tablespace files. In the data directory or the InnoDB data home directory, delete all the `ibdata` and `ib_log` files as well as any file with an `.ibd` or `.frm` extension.
Once this is done, restart the server and import the dump file:

```
$ mysql -u root -p < full-backup.sql
```

Using Raw Disk Partitions

Instead of having InnoDB write to the file system, you can set it to use raw disk partitions. On Windows and some Linux distributions, this allows you to perform non-buffered I/O without the file system overhead. Note that in many use cases this may not actually improve performance. Run tests to verify if there are any real gains for your application usage.

To enable a raw disk partition, first start MariaDB with the `newraw` option set on the tablespace:

```
[mariadb]
...
innodb_data_file_path=/dev/sdc:10Gnewraw
```

When the MariaDB Server starts, it initializes the partition. Don't create or change any data, (any data written to InnoDB at this stage are lost on restart). Once the server has successful started, stop it then edit the configuration file again, changing the `newraw` keyword to `raw`.

```
[mariadb]
...
innodb_data_file_path=/dev/sdc:10Graw
```

When you start MariaDB again, it'll read and write InnoDB data to the given disk partition instead of the file system.

Raw Disk Partitions on Windows

When defining a raw disk partition for InnoDB on the Windows operating system, use the same procedure as defined above, but when defining the path for the innodb_data_file_path system variable, use `./` at the start:

```
[mariadb]
...
innodb_data_file_path=//./E::10Graw
```

The given path is synonymous with the Windows syntax for accessing the physical drive.

System Tables within the InnoDB System Tablespace

InnoDB creates some system tables within the InnoDB System Tablespace:

- `SYS_DATAFILES`
- `SYS_FOREIGN`
- `SYS_FOREIGN_COLS`
- `SYS_TABLESPACES`
- `SYS_VIRTUAL`
- `SYS_ZIP_DICT`
- `SYS_ZIP_DICT_COLS`

These tables cannot be queried. However, you might see references to them in some places, such as in the INNODB_SYS_TABLES table in the information_schema database.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Temporary Tablespaces

When the user creates a temporary table using the CREATE TEMPORARY TABLE statement and the engine is set as InnoDB, MariaDB creates a temporary tablespace file. When the table is not compressed, MariaDB writes to a shared temporary tablespace as defined by the innodb_temp_data_file_path system variable. MariaDB does not allow the creation of `ROW_FORMAT=COMPRESSED` temporary tables. All temporary tables are uncompressed. MariaDB deletes temporary tablespaces when the server shuts down gracefully and is recreated when it starts again. It cannot be placed on a raw device.

Internal temporary tablespaces, (that is, temporary tables that cannot be kept in memory) use either Aria or MyISAM, depending on the aria_used_for_temp_tables system variable. You can set the default storage engine for user-created temporary tables using the default_tmp_storage_engine system variable.

Prior to MariaDB 10.2, temporary tablespaces existed as part of the InnoDB system tablespace or were file-per-table depending on the configuration of the innodb_file_per_table system variable.

Syntax for the value of the innodb_temp_data_file_path variable

The options for innodb_temp_data_file_path is one path or a set of paths, separated by ';'.

The syntax for each path is:

```
path:size[:autoextend][:max:size][:autoshrink]
```

`size` can have extensions 'G' (Gigabytes), 'M' (Megabytes) or 'K' (Kilobytes). If no extension is given, then megabytes is assumed.

- The first `size` argument is the initial size of the temporary table space.
- `autoextend` means that the file size will automatically increase if needed.

- `max` can be used to limit the total size of the temporary file if `autoextend` is used.
- `autoshrink` means that the file will shrink to original size when possible.

Only the last path can have the `autoextend` , `max` and `autoshrink` options.

Sizing Temporary Tablespaces

In order to size temporary tablespaces, use the innodb_temp_data_file_path system variable. This system variable can be specified as a command-line argument to mysqld or it can be specified in a relevant server option group in an option file:

```
[mariadb]
...
innodb_temp_data_file_path=ibtmp1:32M:autoextend
```

This system variable's syntax is the same as the innodb_data_file_path system variable. That is, a file name, size and option. By default, it writes a 12MB autoextending file to `ibtmp1` in the data directory.

To increase the size of the temporary tablespace, you can add a path to an additional tablespace file to the value of the innodb_temp_data_file_path system variable. Providing additional paths allows you to spread the temporary tablespace between multiple tablespace files. The last file can have the `autoextend` attribute, which ensures that you won't run out of space:

```
[mariadb]
...
innodb_temp_data_file_path=ibtmp1:32M;ibtmp2:32M:autoextend
```

Unlike normal tablespaces, temporary tablespaces are deleted when you stop MariaDB. To shrink temporary tablespaces to their minimum sizes, restart the server.

Shrinking the Tablespace

From MariaDB 11.3.0, the temporary tablespace can be shrunk by setting innodb_truncate_temporary_tablespace_now to `ON`:

```
SET GLOBAL innodb_truncate_temporary_tablespace_now=1;
```

InnoDB Troubleshooting

See InnoDB Troubleshooting Overview.

A starting point for diagnosing InnoDB issues, recommending checks on error logs, deadlocks, and table integrity using various tools.

See InnoDB Data Dictionary Troubleshooting.

Learn how to resolve inconsistencies between the InnoDB internal data dictionary and the file system, such as orphan .frm or .ibd files.

See InnoDB Recovery Modes.

Understand the different `innodb_force_recovery` levels, which allow you to start the server in read-only modes to recover data after a crash.

This page is licensed: CC BY-SA / Gnu FDL

InnoDB Troubleshooting Overview

As with most errors, first take a look at the contents of the MariaDB error log. If dealing with a deadlock, setting the innodb_print_all_deadlocks option (off by default) will output details of all deadlocks to the error log.

It can also help to enable the various InnoDB Monitors relating to the problem you are experiencing. There are four types: the standard InnoDB monitor, the InnoDB Lock Monitor, InnoDB Tablespace Monitor and the InnoDB Table Monitor.

Running CHECK TABLE will help determine whether there are errors in the table.

For problems with the InnoDB Data Dictionary, see InnoDB Data Dictionary Troubleshooting.

InnoDB Data Dictionary Troubleshooting

Can't Open File

If InnoDB returns something like the following error:

```
ERROR 1016: Can't open file: 'x.ibd'. (errno: 1)
```

it may be that an orphan `.frm` file exists. Something like the following may also appear in the error log:

```
InnoDB: Cannot find table test/x from the internal data dictionary
InnoDB: of InnoDB though the .frm file for the table exists. Maybe you
InnoDB: have deleted and recreated InnoDB data files but have forgotten
InnoDB: to delete the corresponding .frm files of InnoDB tables?
```

If this is the case, as the text describes, delete the orphan `.frm` file on the filesystem.

Could not find a valid tablespace file

In this case the table definition, the `.frm` file, is missing and the InnoDB dictionary expects it to be there. To remove the InnoDB dictionary entry, the existence of the file needs to faked and then dropped. The existence of the file is faked by creating the `tablename.frm` and potential the database directory if it is missing. Then a `DROP TABLE` or `DROP DATABASE` can be executed which will remove the InnoDB dictionary entry.

Use the query to identify potentially other tablespaces that are known but missing with:

```
SELECT * FROM INFORMATION_SCHEMA.INNODB_SYS_TABLES WHERE NAME LIKE 'dbname/%';
```

Removing Orphan Intermediate Tables

An orphan intermediate table may prevent you from dropping the tablespace even if it is otherwise empty, and generally takes up unnecessary space.

It may come about if MariaDB exits in the middle of an ALTER TABLE … ALGORITHM=INPLACE operation. They are listed in the INFORMATION_SCHEMA.INNODB_SYS_TABLES table, and always start with an `#sql-ib` prefix. The accompanying `.frm` file also begins with `#sql-`, but has a different name.

To identify orphan tables, run:

```
SELECT * FROM INFORMATION_SCHEMA.INNODB_SYS_TABLES WHERE NAME LIKE '%#sql%';
```

When innodb_file_per_table is set, the `#sql-*.ibd` file will also be visible in the database directory.

To remove an orphan intermediate table:

- Rename the `#sql-*.frm` file (in the database directory) to match the base name of the orphan intermediate table, for example:

```
mv #sql-36ab_2.frm #sql-ib87-856498050.frm
```

- Drop the table, for example:

```
DROP TABLE `#mysql50##sql-ib87-856498050`;
```

InnoDB Recovery Modes

The InnoDB recovery mode is a mode used for recovering from emergency situations. You should ensure you have a backup of your database before making changes in case you need to restore it. The innodb_force_recovery server system variable sets the recovery mode. A mode of 0 is normal use, while the higher the mode, the more stringent the restrictions. Higher modes incorporate all limitations of the lower modes.

The recovery mode should never be set to a value other than zero except in an emergency situation.

Please note that recovery mode does not repair corruption. The corrupted files remain corrupted regardless of recovery mode. The sole purpose of recovery mode is to allow read access to the data, if at all possible.

Generally, it is best to start with a recovery mode of 1, and increase in single increments if needs be. With a recovery mode < 4, only corrupted pages should be lost. With 4, secondary indexes could be corrupted. With 5, results could be inconsistent and secondary indexes could be corrupted (even if they were not with 4). A value of 6 leaves pages in an obsolete state, which might cause more corruption.

Until MariaDB 10.2.7, mode `0` was the only mode permitting changes to the data. From MariaDB 10.2.7, write transactions are permitted with mode `3` or less.

To recover the tables, you can execute SELECTs to dump data, and DROP TABLE (when write transactions are permitted) to remove corrupted tables.

The following modes are available:

Recovery Modes

Recovery mode behaviour differs between versions (`server/storage/innobase/include/srv0srv.h`).

CURRENT

Mode	Description
0	The default mode while InnoDB is running normally. Write transactions are permitted with innodb_force_recovery<=4.

Mode	Description
1	(SRV_FORCE_IGNORE_CORRUPT) allows the server to keep running even if corrupt pages are detected. It does so by making redo log based recovery ignore certain errors, such as missing data files or corrupted data pages. Any redo log for affected files or pages are skipped. You can facilitate dumping tables by getting the SELECT * FROM table_name statement to jump over corrupt indexes and pages.
2	(SRV_FORCE_NO_BACKGROUND) stops the master thread from running, preventing a crash that occurs during a purge. No purge are performed, so the undo logs will keep growing.
3	(SRV_FORCE_NO_TRX_UNDO) does not roll back DML transactions after the crash recovery. Does not affect rollback of currently active DML transactions. Will also prevent some undo-generating background tasks from running. These tasks could hit a lock wait due to the recovered incomplete transactions whose rollback is being prevented.
4	(SRV_FORCE_NO_DDL_UNDO) does not roll back transactions after the crash recovery. Does not affect rollback of currently active transactions. Will also prevent some undo-generating background tasks from running. These tasks could hit a lock wait due to the recovered incomplete transactions whose rollback is being prevented.
5	(SRV_FORCE_NO_UNDO_LOG_SCAN) treats incomplete transactions as committed, and does not look at the undo logs when starting. Any DDL log for InnoDB tables are essentially ignored by InnoDB, but the server will start up
6	(SRV_FORCE_NO_LOG_REDO) does not perform redo log roll-forward as part of recovery. Running queries that require indexes are likely to fail with this mode active. However, if a table dump still causes a crash, you can try using a SELECT * FROM tab ORDER BY primary_key DESC to dump all the data portion after the corrupted part.

< 10.6.5

Mode	Description
0	The default mode while InnoDB is running normally. Write transactions are permitted with innodb_force_recovery<=4.
1	(SRV_FORCE_IGNORE_CORRUPT) allows the server to keep running even if corrupt pages are detected. It does so by making redo log based recovery ignore certain errors, such as missing data files or corrupted data pages. Any redo log for affected files or pages are skipped. You can facilitate dumping tables by getting the SELECT * FROM table_name statement to jump over corrupt indexes and pages.
2	(SRV_FORCE_NO_BACKGROUND) stops the master thread from running, preventing a crash that occurs during a purge. No purge are performed, so the undo logs will keep growing.
3	(SRV_FORCE_NO_TRX_UNDO) does not roll back transactions after the crash recovery. Does not affect rollback of currently active transactions. Will also prevent some undo-generating background tasks from running. These tasks could hit a lock wait due to the recovered incomplete transactions whose rollback is being prevented.
4	(SRV_FORCE_NO_IBUF_MERGE) The same as 3.
5	(SRV_FORCE_NO_UNDO_LOG_SCAN) treats incomplete transactions as committed, and does not look at the undo logs when starting.
6	(SRV_FORCE_NO_LOG_REDO) does not perform redo log roll-forward as part of recovery. Running queries that require indexes are likely to fail with this mode active. However, if a table dump still causes a crash, you can try using a SELECT * FROM tab ORDER BY primary_key DESC to dump all the data portion after the corrupted part.

< 10.5

Mode	Description
0	The default mode while InnoDB is running normally. Until MariaDB 10.2.7, it was the only mode permitting changes to the data. From MariaDB 10.2.7, write transactions are permitted with innodb_force_recovery<=3.
1	(SRV_FORCE_IGNORE_CORRUPT) allows the server to keep running even if corrupt pages are detected. It does so by making redo log based recovery ignore certain errors, such as missing data files or corrupted data pages. Any redo log for affected files or pages are skipped. You can facilitate dumping tables by getting the SELECT * FROM table_name statement to jump over corrupt indexes and pages.

Mode	Description
2	(SRV_FORCE_NO_BACKGROUND) stops the master thread from running, preventing a crash that occurs during a purge. No purge are performed, so the undo logs will keep growing.
3	(SRV_FORCE_NO_TRX_UNDO) does not roll back transactions after the crash recovery. Does not affect rollback of currently active transactions. Starting with MariaDB 10.2.7, will also prevent some undo-generating background tasks from running. These tasks could hit a lock wait due to the recovered incomplete transactions whose rollback is being prevented.
4	(SRV_FORCE_NO_IBUF_MERGE) does not calculate tables statistics and prevents insert buffer merges.
5	(SRV_FORCE_NO_UNDO_LOG_SCAN) treats incomplete transactions as committed, and does not look at the undo logs when starting.
6	(SRV_FORCE_NO_LOG_REDO) does not perform redo log roll-forward as part of recovery. Running queries that require indexes are likely to fail with this mode active. However, if a table dump still causes a crash, you can try using a SELECT * FROM tab ORDER BY primary_key DESC to dump all the data portion after the corrupted part.

Note also that XtraDB (<= MariaDB 10.2.6) by default will crash the server when it detects corrupted data in a single-table tablespace. This behaviour can be changed - see the innodb_corrupt_table_action system variable.

Fixing Things

Try to set innodb_force_recovery to 1 and start mariadb. If that fails, try a value of “2”. If a value of 2 works, then there is a chance the only corruption you have experienced is within the innodb “undo logs”. If that gets mariadb started, you should be able to dump your database with mariadb-dump. You can verify any other issues with any tables by running mariadb-check –all-databases.

If you were able to successfully dump your databases, or had previously known good backups, drop your database(s) from the mariadb command line like “DROP DATABASE yourdatabase”. Stop mariadb. Go to /var/lib/mysql (or wherever your mysql data directory is located) and “rm -i ib*”. Start mariadb, create the database(s) you dropped (“CREATE DATABASE yourdatabase”), and then import your most recent dumps: “mysql < mydatabasedump.sql”

Configure the InnoDB Buffer Pool

Overview

In MariaDB Enterprise Server, the InnoDB storage engine uses the Buffer Pool as an in-memory cache. The Buffer Pool caches pages that were recently accessed. If a lot of pages are being accessed sequentially, the Buffer Pool also preemptively caches nearby pages. Pages are evicted using a least recently used (LRU) algorithm.

The contents of the Buffer Pool can be reloaded at startup, so that InnoDB does not have to function with a “cold” cache after a restart. To support this, the page numbers of all pages in the Buffer Pool can be dumped at shutdown. During startup, the page numbers are read from the dump, and InnoDB uses the page numbers to reload each page from its corresponding data file.

The size of each page in the Buffer Pool depends on the value of the innodb_page_size system variable.

Starting with ES 10.5 and CS 10.5, the Buffer Pool always has a single instance.

For additional information, see “InnoDB Buffer Pool”.

This page describes how to configure the InnoDB Buffer Pool.

Configure the InnoDB Buffer Pool Size

The size of the InnoDB Buffer Pool can be configured by setting the innodb_buffer_pool_size system variable. On ES nodes that exclusively use the InnoDB storage engine, the InnoDB Buffer Pool should usually be between 50%-75% of the memory available.

Available Memory	Recommended InnoDB Buffer Pool Size
4 GB	2 GB
8 GB	4-8 GB
16 GB	8-12 GB
32 GB	16-24 GB
64 GB	32-56 GB
128 GB	64-96 GB
256 GB	128-192 GB

The method to configure the Buffer Pool size depends on whether a server restart are performed:

Product Versions	Server Restart?	Method
Any ES Any CS	No	Configure size with SET GLOBAL.
Any ES Any CS	No	Configure size in configuration file

Configure the InnoDB Buffer Pool Size with SET GLOBAL

The size of the InnoDB buffer pool can be changed dynamically by setting the innodb_buffer_pool_size system variable using the SET GLOBAL statement. The SET GLOBAL statement requires the SUPER privilege.

To ensure that the change survives server restarts, the innodb_buffer_pool_size system variable should also be set in a configuration file.

To configure the InnoDB Buffer Pool with the SET GLOBAL statement, use the following procedure:

1. Connect to the server using MariaDB Client as the `root@localhost` user account or another user account with the SUPER privilege:

```
$ mariadb --user=root
```

2. Set the innodb_buffer_pool_size system variable to the new size using the SET GLOBAL statement.

For example, to set the size to 2 GB:

```
SET GLOBAL innodb_buffer_pool_size=(2 * 1024 * 1024 * 1024);
```

3. Confirm that the resize operation has been completed by querying the Innodb_buffer_pool_resize_status status variable using the SHOW GLOBAL STATUS statement:

```
SHOW GLOBAL STATUS
   LIKE 'Innodb_buffer_pool_resize_status';
```

```
+----------------------------------+----------------------------------------------------+
| Variable_name                    | Value                                              |
+----------------------------------+----------------------------------------------------+
| Innodb_buffer_pool_resize_status | Completed resizing buffer pool at 200904 17:49:48. |
+----------------------------------+----------------------------------------------------+
```

4. Choose a configuration file for custom changes to system variables and options.
   It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the z- prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

5. Set the innodb_buffer_pool_size system variable in the configuration file.
   It needs to be set in a group that are read by MariaDB Server, such as [mariadb] or [server].
   When set in a configuration file, the value supports units, such as "M", "G", etc.

For example, to set the size to 2 GB:

```
[mariadb]
...
innodb_buffer_pool_size=2G
```

Configure the InnoDB Buffer Pool Size in a Configuration File

The size of the InnoDB Buffer Pool can be changed by setting the innodb_buffer_pool_size system variable in a configuration file.

To configure the InnoDB Buffer Pool in a configuration file, use the following procedure:

1. Choose a configuration file for custom changes to system variables and options.
   It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.
   Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the z- prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

2. Set the innodb_buffer_pool_size system variable in the configuration file.

It needs to be set in a group that are read by MariaDB Server, such as [mariadb] or [server].

When set in a configuration file, the value supports units, such as "M", "G", etc.

For example, to set the size to 2 GB:

```
[mariadb]
...
innodb_buffer_pool_size=2G
```

3. Restart the server:

```
$ sudo systemctl restart mariadb
```

The server can use the configuration change without a restart if you use SET GLOBAL.

This page is: Copyright © 2026 MariaDB. All rights reserved.

Configure the InnoDB I/O Threads

Overview

The InnoDB Read I/O Threads handle completion of read I/O requests, and the InnoDB Write I/O Threads handle completion of write I/O requests.

Starting with MariaDB Enterprise Server 10.5 and MariaDB Community Server 10.5, the InnoDB I/O Threads were replaced by the asynchronous I/O functionality in the InnoDB Background Thread Pool.

For additional information, see "InnoDB I/O Threads".

This page describes how to configure the InnoDB I/O Threads.

Configure the Number of InnoDB I/O Threads

Starting with ES 10.5 and CS 10.5, the InnoDB I/O Threads have been replaced by the asynchronous I/O functionality in the InnoDB Background Thread Pool. In these versions, the innodb_read_io_threads and innodb_write_io_threads system variables have been repurposed. The value of each system variable is multiplied

by 256 to determine the maximum number of concurrent asynchronous I/O requests that can be completed by the Background Thread Pool.

For example, if `innodb_read_io_threads=2 and innodb_write_io_threads=4` are set, InnoDB are restricted to a maximum of 512 concurrent asynchronous read I/O requests and 1024 concurrent asynchronous write I/O requests.

Interaction with Asynchronous I/O

When asynchronous I/O is enabled, the InnoDB I/O Threads do not receive the initial I/O request from query threads. Instead, the query threads submit asynchronous I/O requests directly to the operating system, and after the operating system performs the operation, the InnoDB I/O Threads handle completion of the request.

Asynchronous I/O is enabled by the innodb_use_native_aio system variable, which is enabled by default.

Affected I/O Operations

The innodb_read_io_threads system variable affects completion of the following types of reads:

- Linear read-ahead (configured by innodb_read_ahead_threshold)
- Random read-ahead (configured by innodb_random_read_ahead)

The innodb_write_io_threads system variable affects completion of the following types of writes:

- Page flushing due to adaptive flushing (configured by innodb_adaptive_flushing and innodb_adaptive_flushing_lwm)
- Page flushing due to buffer pool capacity (configured by [innodb_max_dirty_pages_pct] and [innodb-system-variables/#innodb_max_dirty_pages_pct_lwm|innodb_max_dirty_pages_pct_lwm)
- Page flushing due to LRU page evictions (configured by innodb_lru_flush_size and innodb_lru_scan_depth)

Configuration Procedure

The method to configure the number of I/O threads depends on the server version and whether a server restart are performed:

Product Versions	Server Restart?	Method
ES 10.5 and Later	No	Configure maximum number of asynchronous I/O requests with SET GLOBAL
Any ES Any CS	Yes.	Configure number of I/O threads in configuration file

Configure InnoDB's Maximum Number of Asynchronous I/O Requests with SET GLOBAL (ES 10.5) and Later

Starting with MariaDB Enterprise Server 10.5, InnoDB's maximum number of asynchronous I/O requests can be changed dynamically by setting the innodb_read_io_threadsinnodb_write_io_threads system variables using the SET GLOBAL statement. The SET GLOBAL statement requires the SUPER privilege.

The value of each system variable is multiplied by 256 to determine the maximum number of asynchronous I/O requests that can be performed by the Background Thread Pool. For example, if you want to allow a maximum of 1024 concurrent asynchronous write I/O requests, the innodb_write_io_threads system variable should be set to 4 (since 1024/256=4).

To ensure that the change survives server restarts, the innodb_read_io_threads innodb_write_io_threads system variables should also be set in a configuration file.

To configure InnoDB's maximum number of asynchronous I/O requests with the SET GLOBAL statement, use the following procedure:

1. Connect to the server using MariaDB Client as the `root@localhost` user account or another user account with the SUPER privilege:

```
$ mariadb --user=root
```

2. Set the innodb_read_io_threads and innodb_write_io_threads system variables to the new values using the SET GLOBAL statement.

For example:

```
SET GLOBAL innodb_read_io_threads=8;
SET GLOBAL innodb_write_io_threads=8;
```

3. Choose a configuration file for custom changes to system variables and options.

It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the z- prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

4. Set the innodb_read_io_threads and innodb_write_io_threads system variables in the configuration file.

It needs to be set in a group that are read by MariaDB Server, such as [mariadb] or [server].

For example:

```
[mariadb]
...
innodb_read_io_threads=8
innodb_write_io_threads=8
```

Configure the Number of InnoDB I/O Threads in a Configuration File

The number of I/O threads is configured by the innodb_read_io_threads and innodb_write_io_threads system variables.

To configure the number of InnoDB I/O Threads in a configuration file, use the following procedure:

1. Choose a configuration file for custom changes to system variables and options.

It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the z- prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

2. Set the innodb_read_io_threads and innodb_write_io_threads system variables in the configuration file.

It needs to be set in a group that are read by MariaDB Server, such as `[mariadb]` or `[server]`.

For example:

```
[mariadb]
...
innodb_read_io_threads=8
innodb_write_io_threads=8
```

3. Restart the server:

```
$ sudo systemctl restart mariadb
```

Starting with MariaDB Enterprise Server 10.5, the server can use the configuration change without a restart if you use SET GLOBAL.

Configure the InnoDB Purge Threads

Overview

In MariaDB Enterprise Server, the InnoDB storage engine uses Purge Threads to perform garbage collection in the background. The Purge Threads are related to multi-version concurrency control (MVCC).

The Purge Threads perform garbage collection of various items:

The Purge Threads perform garbage collection of the InnoDB Undo Log. When a row is updated in the clustered index, InnoDB updates the values in the clustered index, and the old row version is added to the Undo Log. The Purge Threads scan the Undo Log for row versions that are not needed by open transactions and permanently delete them.

The Purge Threads perform garbage collection of index records. When an indexed column is updated, InnoDB creates a new index record for the updated value in each affected index, and the old index records are delete-marked. When the primary key column is updated, InnoDB creates a new index record for the updated value in every index, and each old index record is delete-marked. The Purge Threads scan for delete-marked index records and permanently delete them.

The Purge Threads perform garbage collection of freed overflow pages. BLOB, CHAR, TEXT, VARCHAR, VARBINARY, and related types are sometimes stored on overflow pages. When the value on the overflow page is deleted or updated, the overflow page is no longer needed. The Purge Threads delete these freed overflow pages.

For additional information, see “InnoDB Purge Threads”.

This page describes how to configure the InnoDB Purge Threads.

Configure the Number of InnoDB Purge Threads

The number of the InnoDB Purge Threads is configurable. If your server deletes or updates rows at a very high frequency, then you may need to increase the number of purge threads.

The method to configure the number of Purge Threads depends on the server version and whether a server restart are performed:

Product Versions	Server Restart?	Method
ES 10.5 and Later	No	Configure maximum number of asynchronous I/O requests with SET GLOBAL
Any ES Any CS	Yes.	Configure number of I/O threads in configuration file

Configure the Number of InnoDB Purge Threads with SET GLOBAL

> **Note:**
>
> This feature is available from MariaDB Enterprise Server 10.5.

The number of InnoDB purge threads can be changed dynamically by setting the innodb_purge_threads system variable using the SET GLOBAL statement. The SET GLOBAL statement requires the SUPER privilege.

To ensure that the change survives server restarts, the innodb_purge_threads system variable should also be set in a configuration file.

To configure the number of InnoDB Purge threads with the SET GLOBAL statement, use the following procedure:

1. Connect to the server using MariaDB Client as the `root@localhost` user account or another user account with the SUPER privilege:

```
$ mariadb --user=root
```

2. Set the innodb_purge_threads system variable to the new size using the SET GLOBAL statement.

For example:

```
SET GLOBAL innodb_purge_threads=8;
```

3. Choose a configuration file for custom changes to system variables and options.
   It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the `z-` prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

4. Set the innodb_purge_threads system variable in the configuration file.
   It needs to be set in a group that are read by MariaDB Server, such as [mariadb] or [server].

For example:

```
[mariadb]
...
innodb_purge_threads=8
```

Configure the Number of InnoDB Purge Threads in a Configuration File

The number of InnoDB Purge Threads can be configured by setting the innodb_purge_threads system variable in a configuration file.

To configure the number of innodb_purge_threads in a configuration file, use the following procedure:

1. Choose a configuration file for custom changes to system variables and options.
   It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

2. Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the `z-` prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

2. Set the innodb_purge_threads system variable in the configuration file.
   It needs to be set in a group that are read by MariaDB Server, such as `[mariadb]` or `[server]`.

For example:

```
[mariadb]
...
innodb_purge_threads=8
```

3. Restart the server:

```
$ sudo systemctl restart mariadb
```

The server can use the configuration change without a restart if you use SET GLOBAL.

Configure the InnoDB Redo Log

Overview

In MariaDB Enterprise Server, the InnoDB storage engine uses a Redo Log. The Redo Log is a transaction log that InnoDB uses to write data to disk in a crash-safe manner.

Redo Log records are identified using the Log Sequence Number (LSN). The Redo Log is a circular log file that is a constant size. Old Redo Log records are frequently overwritten by new Redo Log records. InnoDB regularly performs checkpoints. During a checkpoint, InnoDB flushes Redo Log records to the InnoDB tablespace files.

When the server crashes, InnoDB performs crash recovery during server startup using the Redo Log. During crash recovery, InnoDB finds the last checkpoint in the Redo Log and flushes the Redo Log records since the last checkpoint to the InnoDB tablespace files.

For additional information, see "InnoDB Redo Log".

This page describes how to configure the InnoDB Redo Log.

Configure the InnoDB Redo Log Size

> **Warning:**
>
> **Do not delete the `ib_logfile` files before startup to resize the redo log.** Starting with **MariaDB 10.8** — and **MariaDB Enterprise Server 11.4**, the first Enterprise Server with this behavior — the server fails to start if its existing redo log files are missing. The server must always be started with its existing redo log files. To resize the redo log, start the server normally, then use `SET GLOBAL innodb_log_file_size=…` (see below). Once the change is applied in the running instance, update the configuration file so the new size persists across restarts. This is part of the InnoDB redo log redesign tracked under MDEV-27199. Manual deletion of `ib_logfile` files was discouraged as early as MySQL 5.6.11 and became a hard startup failure in MariaDB 10.8 / Enterprise Server 11.4.

The size of the InnoDB Redo Log is configurable. If your server writes data at a very high frequency, then you may need to increase the redo log size, so that InnoDB does not have to perform checkpoints as frequently.

For the maximum capacity in the Redo Log, the Redo Log size should be the same as the innodb_buffer_pool_size, which is configured by the innodb_buffer_pool_size system variable.

The method to configure the Redo Log size depends on the server version and whether a server restart are performed:

Product Versions	Server Restart?	Method
ES 10.5 and Later	No	Configure size with SET GLOBAL
ES 10.5 and Later CS 10.5 and Later	Yes	Configure size in configuration file

Configure the InnoDB Redo Log Size with SET GLOBAL (ES 10.5 and Later)

Starting in MariaDB Enterprise Server 10.5, the size of the InnoDB Redo Log can be changed dynamically by setting the innodb_log_file_size system variable using the SET GLOBAL statement. The SET GLOBAL statement requires the SUPER privilege.

The resize operation is performed asynchronously in the background. If the server is restarted before the operation completes, the request may be ignored. To ensure that the change survives server restarts, the innodb_log_file_size system variable should also be set in a configuration file.

To configure the InnoDB Redo Log with the SET GLOBAL statement, use the following procedure:

1. Connect to the server using MariaDB Client as the `root@localhost` user account or another user account with the SUPER privilege:

```
$ mariadb --user=root
```

2. Set the innodb_log_file_size system variable to the new size using the SET GLOBAL statement.

For example, to set the size to 512 MB:

```
SET GLOBAL innodb_log_file_size=(512 * 1024 * 1024);
```

And to set the size to 2 GB:

```
SET GLOBAL innodb_log_file_size=(2 * 1024 * 1024 * 1024);
```

3. The resize operation is performed asynchronously in the background. Confirm that the resize operation is complete by querying the innodb_log_file_size system variable using the SHOW GLOBAL VARIABLES statement. The resize operation is complete when the output shows the new size as the value of the system variable.

Execute the following statement until it shows the new size:

```
SHOW GLOBAL VARIABLES
   LIKE 'innodb_log_file_size';
```

4. Choose a configuration file for custom changes to system variables and options.
   It is not recommended to make custom changes to Enterprise Server's default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the `z-` prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

5. Set the innodb_log_file_size system variable in the configuration file.

It needs to be set in a group that are read by MariaDB Server, such as [mariadb] or [server].

When set in a configuration file, the value supports units, such as “M”, “G”, etc.

For example, to set the size to 512 MB:

```
[mariadb]
...
innodb_log_file_size=512M
```

And to set the size to 2 GB:

```
[mariadb]
...
innodb_log_file_size=2G
```

Configure the InnoDB Redo Log Size in a Configuration File (ES 10.5) and Later

Starting in MariaDB Enterprise Server 10.5, the size of the InnoDB Redo Log can be changed by setting the innodb_log_file_size system variable in a configuration file.

To configure the InnoDB Redo Log in a configuration file, use the following procedure:

1. Choose a configuration file for custom changes to system variables and options.

It is not recommended to make custom changes to Enterprise Server’s default configuration files, because your custom changes can be overwritten by other default configuration files that are loaded after.

Ensure that your custom changes are read last by creating a custom configuration file in one of the included directories. Configuration files in included directories are read in alphabetical order. Ensure that your custom configuration file is read last by using the `z-` prefix in the file name.

Some example configuration file paths for different distributions are shown in the following table:

Distributions	Example configuration file path
CentOS RHEL Rocky Linux SLES	/etc/my.cnf.d/z-custom-mariadb.cnf
Debian Ubuntu	/etc/mysql/mariadb.conf.d/z-custom-mariadb.cnf

2. Set the innodb_log_file_size system variable in the configuration file.
   It needs to be set in a group that are read by MariaDB Server, such as [mariadb] or [server].
   When set in a configuration file, the value supports units, such as “M”, “G”, etc.

For example, to set the size to 512 MB:

```
[mariadb]
...
innodb_log_file_size=512M
```

And to set the size to 2 GB:

```
[mariadb]
...
innodb_log_file_size=2G
```

3. Starting in MariaDB Community Server 10.5, the server must be restarted for the configuration change to take effect:

```
$ sudo systemctl restart mariadb
```

4. Starting in MariaDB Enterprise Server 10.5, the server can use the configuration change without a restart if you use SET GLOBAL.

Emergency Recovery Across Major Versions

In MariaDB 11.x (and the corresponding MariaDB Enterprise Server releases), starting the server with data files from MariaDB 10.x is permitted **only** when innodb_force_recovery is set to `6`. This path is intended exclusively as a last-resort mechanism for extracting a logical dump from a corrupted or otherwise incompatible database; it is **not** a substitute for the normal upgrade path.

> **Important:**
>
> `innodb_force_recovery=6` places the database in a highly restricted state intended only for data salvage. Do not use it as a standard operational approach or a shortcut for the normal upgrade path.

When this emergency path is in effect:

- The database accepts no new writes or modifications.
- Use mariadb-dump (or another logical export tool) to extract the data, then re-import it into a fresh, supported instance.

For the standard upgrade procedure between major versions, see Upgrading Between Major MariaDB Versions.

This capability was added under MDEV-39303, available in MariaDB 11.4.11, MariaDB 11.8.7, and later releases.

Configure the InnoDB Undo Log

Overview

The InnoDB undo log is a transaction log used by InnoDB to keep track of multiple row versions for multi-version concurrency control (MVCC). When a row's value changes, InnoDB stores old versions of the row in the Undo Log.

When transactions are committed and the old row versions are no longer necessary, the InnoDB Purge Threads asynchronously delete old row versions from the Undo Log in the background.

When a transaction is rolled back, InnoDB uses the Undo Log to rollback the transaction's changes.

For additional information, see "InnoDB Undo Log".

This page describes how to configure the InnoDB Undo Log.

Configure InnoDB Undo Log Tablespaces

By default, the InnoDB undo log is located in the InnoDB system tablespace, which is defined by the innodb_data_file_path system variable. However, it can be helpful to configure separate undo log tablespaces to spread out I/O load between different files or storage devices.

InnoDB can be configured to use separate undo log tablespaces by setting the innodb_undo_tablespaces system variable. The separate undo log tablespaces will have file names of the format undoN, where N is an integer.
